Dr. J. K. A. Bleasdale (National Vegetable Research Station) described his studies of the deleterious effects of air pollution on plant growth, these being particularly severe on winter annuals, which grow at a time when air pollution is at its worst. Dr. Bleasdale discussed the toxic effects of pollution on plants and soils and the effect of smoke haze in reducing light available for photosynthesis. The one redeeming feature in this otherwise gloomy picture is the notable freedom from certain fungal infections of plants growing in polluted air.

Dr. P. J. Lawther (Medical Research Council) pointed out that while acute air pollution is manifestly injurious and even fatal to old people and respiratory cripples, less dramatic consequences such as the hastening of the development of chronic bronchitis must not be overlooked. The chronic pollution suffered by town-dwellers is also suspected as an etiological factor in the production of chronic bronchitis and lung cancer, though in the case of the latter disease air pollution can play only a small part in the alarming increase in its prevalence.

Dr. R. Allcroft (Ministry of Agriculture, Fisheries and Food), reading a paper entitled "Fluorosis in Farm Animals", briefly surveyed the areas of occurrence and the industries with which it is associated. In Britain, fluorosis results exclusively from the aerial contamination of herbage by the emission of gases and dusts containing fluorine. The symptoms of fluorosis in cattle and other farm animals were described and shown on film, and the effects of dental changes and lameness, associated with fluorosis, on the quality of stock were discussed. Adverse environmental factors and physiological stresses greatly influence the severity of the toxic effect and it seems difficult to define damaging pasture concentrations, but a tolerance-level of between 30 and 50 p.p.m. in the food was given.

Mr. R. H. Burns (Atomic Energy Research Establishment), the first speaker in the final session, devoted to pollution by radioactive wastes, outlined the main differences between radioactive and other waste materials, the most important being our inability to destroy the harmful properties of the former by chemical means. Methods of dealing with wastes, disposal and storage, were described. There is an increasing demand for some of the fission products, particularly radiocæsium and radiostrontium, in industry and medicine, and storage of liquid wastes, though expensive, costing £200 per cubic metre, is being used on an increasing scale. Mr. Burns demonstrated by his paper how carefully such factors as the proper siting of effluent pipes and the fixing of permissible levels of discharge are considered in relation to the disposal of radioactive wastes.

Mr. W. L. Templeton (U.K. Atomic Energy Authority) directed attention to the greater hazards that may arise from accumulation of radioactive isotopes from the diluting medium by food-organisms than by direct radiation from the environment. The value of the observational and experimental approaches in the measurement of accumulation factors was outlined and their findings surveyed. Mr. Templeton felt, however, that series of planned experimental discharges, each of several months duration, would be of the greatest value in determining long-term variations and build-up of activity.

Dr. H. J. M. Bowen (Wantage Radiation Laboratory), discussing the uptake of fission products by plants, outlined recent advances in our knowledge of their absorption by various plant structures and their translocation in plant tissues. Dr. Bowen described his work with accumulator plants, that is, plants which concentrate large quantities of specific elements. He found that radiostrontium, the most dangerous fission product, was accumulated particularly by certain species of *Fucus* and *Laminaria*. It would seem that one important gap in our knowledge is that of the relation of rainfall and soil-type to the accumulation of fission products by plants.

In the last paper of the symposium, entitled "Genetic Hazards of Radioactive Pollution", Dr. T. C. Carter (Medical Research Council) suggested that recent work casts doubt on assumptions made by experimental geneticists, based principally on the radiation effects on gene mutation in *Drosophila* sperms. It is on these questionable assumptions that radiation effects are calculated. Dr. Carter stressed the need for an investigation of the relation between rates of mutation and accumulated radiation doses in mammals, particularly in the low-dosage range relevant to man. All present-day assessments of genetic hazards of radiation assume a linear relation. A figure of about £200,000 was quoted as the total outlay necessary for such an investigation. This is surely a small price to pay for such basic and vital information, especially when man's future well-being is at stake.

THE UNIVERSITY GRANTS COMMITTEE

RETURNS FOR 1956–57

THE annual returns from universities and university colleges in receipt of Treasury grants for the academic year 1956–57, published by the University Grants Committee*, records a further increase of 4,672 in the number of full-time students, which now stands at 89,866, compared with 81,705 in 1954–55, and it is expected that the number in 1957–58 will show a greater increase since the number of full-time students in the autumn term of 1957 was 5,899 greater than in the autumn term of 1955. There were 6,115 full-time and 2,016 part-time students from overseas within the British Commonwealth and 3,792 full-time and 1,756 part-time students from foreign countries; for 1955–56 the corresponding figures were 5,536 and 2,068 for the Commonwealth and 3,750 and 1,756 for foreign countries. Distribution of full-time students among the faculties showed no significant change, but the proportion in pure science increased from 21·3 to 22·2 per cent, in technology from 13·3 to 13·9 per cent, and that in medicine decreased from 15·7 to 14·4 per cent. Full-time advanced students of pure science numbered 3,675 (35 per cent); of technology 1,650 (15·7 per cent); and medicine and dentistry 1,041 (9·9 per cent); 2,870 students were working for the teacher's diploma. Of the full-time students, 71,713 were reading for a first degree, 3,969 for a first diploma, and 13,379 engaged in research or other advanced work, the corresponding figures for 1955–56 being 67,850, 4,021 and 12,668.

The proportion of assisted students was 75·7 per cent compared with 74·9 per cent in 1955–56 and 71·9 per cent in 1953–54, ranging from 90·4 per cent in Wales, 83·8 per cent for English universities and university colleges, excluding Oxford, Cambridge and London, to 61·7 per cent for Scotland. Of the recurrent income of £41,635,609 (an increase of £3,338,958 on 1955–56), £29,082,526 was from parliamentary grants (69·8 per cent). Income from fees decreased from 11·2 to 10·8 per cent, local authority grants increased from 2·9 to 3·1 per cent, payments for research from 6·0 to 6·5 per cent, gifts and subscriptions from 1·0 to 1·2 per cent, and endowments were again 4·0 per cent. Full-time teaching staff increased to 10,485, compared with 10,202 in 1955–56 and 9,810 in 1954–55.

The proportion of full-time students residing in colleges and halls of residence was 27·4 per cent, compared with 27·5 in 1955–56, but the total, 24,652, was higher. The proportion of men in residence was 23·2 per cent and of women 39·9 per cent; whereas 41,291 (46·0 per cent) were in lodgings and 23,923 (26·6 per cent) at home, compared with 44·7 per cent and 27·8 per cent, respectively, in the previous year. Non-recurrent grants in respect of capital expenditure totalled £9,134,185, compared with £7,084,366 in 1955–56, and of the recurrent expenditure of £41,509,703—an increase of 9·1 per cent on 1955–56 —7·0 per cent was spent on administration, 68·4 per cent on departmental maintenance, and 12·9 per cent on maintenance of premises. The largest increases were in rates, insurance, heat, light, water, wages, etc. (15·3 per cent), departmental wages (technicians and laboratory assistants) (14 per cent), and in repairs and maintenance of buildings (13·9 per cent). Expenditure on libraries (excluding general maintenance, rates, etc.) increased from £1,468,512 to £1,620,958 but remained at 3·9 per cent of the total.

SCIENTIFIC FILMS AT THE BRITISH ASSOCIATION

FOR the fourth successive year the Scientific and Technical Group of the Royal Photographic Society of Great Britain, in conjunction with the Scientific Films Committee of the British Association, presented a series of research films as part of the annual meeting of the British Association. These films were shown in two sessions during the morning and afternoon of August 30. The morning session was under the chairmanship of Sir Raymond Priestley, and during the afternoon Mr. Bowler, vice-president of the Society, took the chair.

Several films were devoted to biological subjects, from the study of the mating behaviour of marsupial frogs to the investigation of cancerous cells. The muscle structure of sea-anemones, courtship of *Drosophila melanogaster*, nematodes and *Leishmania donovani* were also objects of investigation. In what might be described as the industrial field many problems have been covered with ciné techniques, including the casting of steel, coke-oven performance, vehicle suspension systems, flooring research, bookbinding operations and the flow of water in large pipes.

From the psychological aspect, two films were shown which demonstrated techniques that have been employed to identify the particular point of a general scene at which a subject is looking, thus enabling eye co-ordination to be studied. Also in this field an extract was shown from a film which studied parent/child relationship in an experimental treatment of the problems involved in admission to hospital of children under school age.

In pure physics, the motion of electrons in electric fields was demonstrated by means of charged droplets; this film was made in Germany. Automatic self-replication was also shown by ingenious systems of models. Finally, Mr. Hallett, secretary of the Society, gave a short talk on the scope and aims of the "Encyclopædia Cinematographica", with examples of research films loaned by Dr. Wolf, of Göttingen.

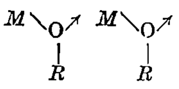
Among the methods used to prepare these films were time-lapse and high-speed ciné-photography, interference and phase-contrast microscopy, electron microscopy and television techniques. Colour and monochrome, silent and sound-track films were all represented at this meeting, which admirably demonstrated the wide variety of ways in which photography can be of use in research in an equally wide range of scientific investigation.

A more detailed report will be published in the *Journal of Photographic Science.*

A STRUCTURAL THEORY FOR METAL ALKOXIDE POLYMERS

By DR. D. C. BRADLEY
Department of Chemistry, Birkbeck College, University of London

RECENT studies[1,2] on the metal alkoxides $M(OR)_n$, where M is an n-valent metal and R is an alkyl group, have established that derivatives with the lower primary or secondary alkyl groups are in fact polymeric, that is $\{M(OR)_n\}_x$, where x is the degree of polymerization. It is believed that this polymerization is caused by intermolecular bonds involving the metal and oxygen atoms, namely:



and is a manifestation of the tendency of the metal to expand its covalency by co-ordination with oxygen. It is a striking feature of the metal alkoxides that the alternative mechanism for this covalency expansion, namely, co-ordination between the alkoxide and a ligand containing oxygen or nitrogen (for example, $M(OR)_n,xL$), is relatively rare and this suggests a special stability for the polymer. Moreover, it is a general rule that, in a series of metal alkoxides with metals of the same sub-group (for example, titanium, zirconium, thorium) and having the same alkyl groups, the degree of polymerization x increases with the size of the metal atom. Nevertheless, only in a few cases have structures been suggested for metal alkoxide polymers[3-7]. Another interesting feature of these compounds is that the polymers are relatively small compared with typical organic polymers and silicones. Recent studies on the hydrolysis of titanium alkoxides[8,9] showed that the titanium oxide alkoxides $TiO_h(OR)_{4-2h}$ formed were also low polymers, and this behaviour was explained in terms of a series of structural models in which titanium was 6-co-ordinated by oxygen. Further consideration of these structures reveals that in each case the degree of polymerization is unique in being the lowest possible, and this led me to explore the possibility of rationalizing the polymeric nature of metal alkoxides in terms of the stereochemistry of the metal. It is the purpose of this article to show that a rationalization can indeed be achieved on the basis of the following single new major assumption. It is assumed that the metal alkoxide adopts the smallest possible structural unit consistent with all the metal atoms attaining a higher co-ordination number. Also the choice of structure is limited by the condition that the co-ordination number of oxygen does not exceed

Table 1

Compound	Co-ordination No. of M	Stereochemistry of M	Minimum degree of polymer-ization
MOR	2	$OMO = 90°$	2
	2	$OMO = 120°$	3
	3	Pyramidal	4*
$M(OR)_2$	3	Planar, one $OMO = 90°$	2
	3	Planar, $OMO = 120°$	3
	4	Tetrahedral	3
	4	Planar	4
	6	Octahedral	Infinite 3-dimensional polymer
$M(OR)_3$	4	Tetrahedral	2*
	4	Planar	2
	6	Octahedral	8*
$M(OR)_4$	5	Trigonal bipyramidal	2
	6	Octahedral	3*
	8	Cubic	8
$M(OR)_5$	6	Octahedral	2*
	8	Cubic	4
$M(OR)_6$	8	Cubic	2*

* Agrees exactly with predictions of the theory

four. Then the degree of polymerization can be predicted in terms of the stereochemistry of the metal. Some typical deductions from this theory are given in Table 1 and it is clear that in general the polymers predicted are very low ones. Next we shall see how far the experimental evidence supports this theory. Unfortunately there are to date no direct structural determinations available on metal alkoxides and we can only compare the predicted degree of polymerization with that determined cryoscopically or ebullioscopically, bearing in mind that these experimental values are averages.

Univalent Metal Alkoxides

Sidgwick and Sutton[3] found that thallous alkoxides were tetrameric and proposed a structure in which each thallium atom was bonded pyramidally to three oxygens and each oxygen was bonded to three thalliums and one alkyl group. This agrees exactly with the above theoretical considerations. No other data are available on univalent metal alkoxides. The alkali metal alkoxides are usually assumed to be ionic, but in view of the covalent nature of alkali metal zirconium ennea-alkoxides[10] there is the possibility that the alkali metals, especially lithium, may form covalent alkoxides. Similarly, it will be worth while to investigate cuprous, argentous and aurous alkoxides.

Bivalent Metal Alkoxides

No data are available on bivalent metal alkoxides although some have been prepared. The case of beryllium is particularly interesting because it is expected to adopt a tetrahedral configuration with oxygen and should thus form trimeric dialkoxides with the structure already proposed[2]. On the other hand, 4-co-ordinated bivalent copper might adopt the planar configuration resulting in cyclic tetrameric cupric alkoxides. A cyclic trimer is unlikely because this would bring the copper atoms too close together.

Tervalent Metal Alkoxides

Aluminium alkoxides are well known and some molecular weights have been determined[4,11,12]. Robinson and Peak[4] proposed a structure for the tetrameric alkoxides involving a cyclic system with 4-co-ordinated aluminium. However, the above theory predicts a dimer for 4-co-ordinated tetrahedral aluminium and there is no obvious reason why a cyclic tetramer should obtain. On the other hand, it is known that aluminium can achieve a maximum co-ordination number of six and for octahedral aluminium the theory predicts an octamer. Thus the tetramers could result from a distribution of the aluminium between 4- and 6-co-ordination.

In fact, the possibility of two higher co-ordination numbers for aluminium is probably the cause of the unusual behaviour of aluminium trialkoxides. For example, Mehrotra[12] has demonstrated an 'ageing effect' in which the degree of polymerization increases with time. Also, a hysteresis effect has been detected in measuring the vapour pressures of aluminium alkoxides[13]. In addition, Mehrotra[12] found that aluminium *iso*propoxide was dimeric in the vapour state. These facts can readily be interpreted on the basis of the structural theory. Assuming that the freshly distilled or sublimed alkoxide is initially dimeric and contains tetrahedral aluminium, then the ageing effect will be due to a structural rearrangement as the aluminium realizes its maximum co-ordination number. Clearly, this rearrangement in a solid at room temperature will be slow and consequently the degree of polymerization of an aluminium alkoxide will depend on its previous history. This could explain the high values reported by Ulich and Nespital[11]. Although the theory predicts the dimer and the octamer for 4- and 6-co-ordinated aluminium, respectively, other unique structures are predicted for systems involving both higher co-ordination numbers. For example, if 75 per cent is 4-co-ordinate and 25 per cent 6-co-ordinate, a tetramer is possible containing a central octahedral aluminium attached through alkoxide bridges to the three tetrahedral aluminiums[2]. This corresponds to the completion of the first distinct stage in the ageing process and it is extremely interesting to note that Robinson and Peak and Mehrotra found tetrameric aluminium alkoxides. The remaining unique structure is a hexamer involving 66·7 per cent 4-co-ordinate and 33·3 per cent 6-co-ordinate aluminium. In this structure[2] the molecule contains two 6-octahedral aluminiums joined through an alkoxide bridge and each one is attached through alkoxide bridges to two tetrahedral aluminiums. The second stage in the ageing process should then result in the formation of this hexamer and the final stage would involve the formation of octamers in which the aluminium is entirely 6-co-ordinated.

Quadrivalent Metal Alkoxides

Titanium tetra-alkoxides have been known for many years, but the first results of structural significance were reported by Caughlan *et al.*[5], who found that these compounds tended to a limiting degree of polymerization of 3 at higher concentrations. They proposed a structure for the trimer (Fig. 1) based on 6-co-ordinated titanium with three octahedra joined together through the sharing of common faces. As can be seen from Table 1, this trimeric structure is in accordance with the predictions of the theory. Even more striking examples of structures which are logical consequences of this theory are the titanium oxide ethoxides $Ti_6O_4(OEt)_{16}$ (Fig. 2) and[8] $Ti_{12}O_{12}(OEt)_{24}$. Although titanium appears limited to a maximum co-ordination number of 6, zirconium, cerium-IV and thorium can achieve a higher co-ordination number of 8. The lowest possible polymer for a tetra-alkoxide containing 8-co-ordinated metal is the octamer involving a cyclic configuration of body-centred cubes (Fig. 3)[14]. The cube was chosen for 8-co-ordination because there are four oxygens on each face and this gives the maximum degree of sharing of alkoxide groups between any two adjacent metal atoms and hence the minimum degree of polymerization. Zirconium normal alkoxides[6] had an average degree of polymerization of 3·5, which is near the predicted value for 6-co-ordinated zirconium. Moreover, zirconium tetra-*iso*propoxide is trimeric and it forms a solvate $Zr(OPr^i)_4,Pr^iOH$, which is dimeric. A structure was proposed for the solvate[6] involving octahedrally 6-co-ordinated zirconium (Fig. 4) and it is interesting to note that this is exactly in accordance with the structural theory. The lower alkoxides of thorium were insoluble, thus precluding molecular weight determinations, but the longer chain normal alkoxides were soluble and exhibited an average degree of polymerization of 6·3, which suggests that the thorium is predominantly 8-co-ordinated. In view of the availability of two higher co-ordination numbers for zirconium, cerium-IV and thorium, it would not be surprising to find ageing effects in their alkoxides (cf. aluminium).

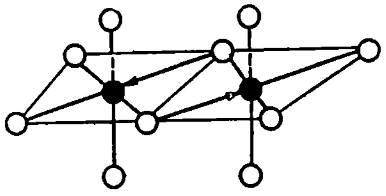

Fig. 5. ●, Tantalum; ○, Oxygen

Quinquevalent Metal Alkoxides

It can be seen from Table 1 that a penta-alkoxide containing an octahedrally 6-co-ordinated metal should be dimeric. Recent work on normal alkoxides of niobium[15] and tantalum[7] showed that they were dimeric and a structure was proposed for the tantalum derivatives in agreement with the theory (Fig. 5). Moreover, a number of uranium penta-alkoxides were also found to be dimeric but the penta methoxide $U(OMe)_5$ was trimeric and it was suggested that in the latter there might be a significant proportion of 8-co-ordinated uranium[15]. Thus the smallest polymer for a penta-alkoxide containing an 8-co-ordinated metal with the cubic configuration would be the tetramer. A tetramer will also result from a square antiprism configuration.

Sexavalent Metal Alkoxides

The theory predicts a dimeric state for a hexa-alkoxide containing an 8-co-ordinated metal with either the cubic body-centred or square antiprism configuration. Measurements on uranium hexamethoxide $U(OMe)_6$ show that it is predominantly dimeric (Bradley, D. C., and Chatterjee, A. K., unpublished work), suggesting that the uranium is 8-co-ordinated.

This survey of experimental data has shown several examples (Table 1) which agree exactly with the predictions of the theory and other cases where the known degree of polymerization is within the limits set by the theory (that is, where more than one higher co-ordination number is available). The variety of examples which fit the theory make it unlikely that the agreement is merely coincidental. Therefore it is interesting to consider why metal alkoxides adopt the structures with the lowest degrees of polymerization and to discover whether this phenomenon is shared with other types of compound. Undoubtedly a factor of fundamental importance is the covalency expansion of the metal, since this causes the polymerization. Thus in the formation of organic high polymers, no change in covalency of carbon is involved, and similarly in the silicones the silicon is essentially quadricovalent although some π-bonding involving 3*d* orbitals of the silicon may contribute to the structure. Another important feature of the metal alkoxides is the relatively low energy (about 10 kcal.) of the intermolecular bonds which hold the polymer together. Clearly the most stable polymer (to thermal dissociation) will be the one containing the maximum number of these weak intermolecular bonds between adjacent units in the polymer. This point can well be illustrated by reference to titanium alkoxides. If all the titanium is octahedrally 6-co-ordinated there is a choice between the trimer in which the octahedra share faces and each unit is held by three intermolecular bonds, and a higher polymer in which the octahedra share edges and each unit is held by two intermolecular bonds. If the intermolecular bond energy is approximately the same in each case, then 50 per cent more energy is required to detach a unit from the trimer molecule than from the higher polymer. According to these ideas the formation of low polymers need not be limited to the metal alkoxides but could be expected wherever the formation of a polymer is due to covalency expansion of an element and wherein the intermolecular bonds are weak. For example, some of the electron-deficient molecules such as the boron hydrides and metal alkyls support this view. Diborane is formed from BH_3 because the tercovalent boron increases its covalency to four. This covalency expansion could be achieved in an infinite linear polymer $(BH_3)_\infty$ in which each unit of the polymer is held by only one hydrogen bridge as against the two in diborane. However, it must be realized that in some systems of inorganic polymers (for example, borazoles and phosphonitrilic compounds) also involving covalency expansion there are other complicating factors such as π-bonding and aromaticity which may stabilize particular structures, and it does not follow that the molecule will adopt the lowest possible degree of polymerization.

It is hoped to test the theory discussed above by direct structural measurements on the metal alkoxides. However, it is always possible that in the crystal lattice a metal alkoxide may adopt a degree of polymerization different from that exhibited in solution.

I am indebted to the Chemical Society for permission to reproduce the diagrams in Figs. 1–5, and also to Prof. W. Wardlaw for his guidance and encouragement throughout this work.

EYE MOVEMENTS AND THE STABILITY OF THE VISUAL WORLD

By R. L. GREGORY

Psychological Laboratory, Downing Place, Cambridge

THE visual perception of movement is generally regarded as of primary biological importance, yet far less work has been done on this subject than on topics such as colour vision, visual acuity and the photic sensitivity of the eye. Further, surprisingly little is reliably known about the neurological mechanisms subserving movement perception. There are many unsettled questions, in particular that of the apparent stability of the visual world during voluntary movements of the eye. Some of the problems raised by the visual perception of movement will be discussed in this article.

Information Channels in the Perception of Movement

The simplest case of movement perception is that given by a moving self-luminous object in a dark room. Perception of its movement may occur under two different sets of conditions: (1) the eyes may follow the object ('tracking'), in which case its image will, ideally, remain stationary upon the retinæ; and (2) the eyes may remain stationary so that the images travel across the retinæ. Since movement is experienced under both conditions, there must be at least two information channels subserving movement perception. The first involves tracking eye movements, and may be called the 'retina/head' system. The second involves shifts of the image across the retina, and may be called the 'image/retina' system. It may be supposed that the two systems are based on essentially different neurological mechanisms.

Movement perceptions may, in special circumstances, be paradoxical. When a fast-flowing river, the view from a moving train, or an endless belt of black-and-white stripes is fixated for several seconds it will be found that if the gaze is transferred to a stationary object it will seem to move in the opposite direction and with corresponding velocities to those of the previously observed real movement. This after-effect of movement is paradoxical, for though movement is clearly observed it may also be seen that nothing is changing in position. Similarly, when a stationary small weak light is observed in total darkness it will seem to move erratically, and yet it may not seem to change its position to any marked extent. Such paradoxical perceptions may be due to incompatible information arriving from the two or more movement channels. Adaptation or random changes in the systems might be the cause.

As is well known, there are two essentially different types of eye movement, first studied systematically by

Dodge[1,2]. When the eye tracks a moving target, once it is 'locked' on to the target it moves smoothly, provided that the target moves in a simple, known manner without excessive changes in direction or velocity. Voluntary movements in the absence of a target take place in small jerks ('saccades') occurring about four times per second, which have been much studied particularly in relation to reading.

It is generally supposed that smooth tracking movements of the eyes occur only in response to retinal cues, that is they form part of what we have called the 'retina/head' system. I have shown that this is not necessarily the case. A small neon lamp is arranged to flash at 25–50 flashes/sec.: the light will appear continuous under conditions of steady fixation, but if, with the eyes remaining still, the lamp is moved steadily across the retina, a regular flicker will be noticed. This is a well-known effect. If now the eye is swept as smoothly as possible by voluntary movement, this regular flicker is not seen. The lamp seems to move in jerks. Evidently the saccadic movements prevent the smooth travel of the image which is necessary for the observation of the regular flicker. On the other hand, when the eyes follow a moving target the flicker may be observed, as when the lamp is moved across the field with the eyes stationary. Using this technique, I have been able to show that it is not necessary for the observer to track a visual object for the smooth eye movements to occur. The regular flicker indicating smooth eye movements may be seen if the observer tries to track his own hand under conditions of complete darkness apart from the light from the neon lamp, his hand being invisible. That is to say, smooth eye movements may be elicited even in the absence of appropriate retinal stimuli. It follows that the retina/head system may involve a proprioceptive component; information from moving members of the body may suffice to actuate the smooth eye movement system. I have also found that the apparent movements of a stationary small weak light viewed in darkness (the 'autokinetic effect') are influenced by slight unbalanced strains imposed on the eye or neck musculature. The effect may normally be due to randomly occurring imbalance of the musculature or proprioceptive systems of the eye and neck.

Eye Movements and Perceptual Stability

It is a commonplace to state that when the eyes move voluntarily across an extended field (by means of saccadic movements) there is little, if any, change in apparent position of the perceived objects. The visual world does not swing round in the direction opposed to the eye movement. On the other hand, nearly all subjects report that when an object moving across the field is tracked, the stationary background does tend to swing round in the opposed direction. The experience is similar to, though probably less marked than, the movement of the field observed when the eye-ball is moved passively by pressure from the finger. This observation suggests that saccadic eye movements are in some way necessary for the stability of the visual world. It may be that the jerky movements of the eye are themselves important, or that the saccadic mechanism accepts information giving rise to stability which is rejected during smooth tracking movements. Evidence to be given below suggests that the former is the case.

The problem of the stability of the visual world was discussed by Helmholtz[3], and later by many other writers, the most recent being Mackay[4]. There have been two main theories. The first, that stabilization is given by proprioceptive information from the extrinsic eye muscles, which has been called the 'inflow' theory, was rejected by Helmholtz, who held that the central command signals (but called by him 'the Will') are monitored by an internal loop which gives appropriate information for providing stability, provided the motor system is functional. This has been called the 'outflow' theory. He pointed out that patients suffering from paralysis of the external recti, and who were therefore unable to execute voluntary eye movements, experience the visual world moving round in the direction in which the eyes should have moved had it been possible to "execute the command". This observation has been confirmed under more controlled conditions[5].

A useful technique for investigating many of the phenomena of stabilization and movement perception is provided by observations of after-images (preferably produced by fixating a photographic-type electronic flash tube) under various conditions. It is not always realized that after-images observed in complete darkness move, apparently rather precisely, with the eyes during slow voluntary eye movements though they are not affected by passive movements. We should expect some feed-back from the stretch receptors which are now known to exist in the eye muscles[6,7] during passive movements, and this should produce some shift of after-images if the inflow theory were true.

We find that if, in total darkness, the drift of an after-image is observed during (*a*) slow voluntary eye movements, and (*b*) during the 'proprioceptive tracking' of the observer's hand described above, the after-image shows small saccadic-like jerks in condition (*a*), but not in condition (*b*), when it moves smoothly. If the velocity of the hand movement is changed the after-image may seem to lead or lag, and then to 'lock' on to the proprioceptive locus of the hand. The jerks experienced in condition (*a*) suggest that the stabilizing system has access to information of saccadic movements.

The Cancellation Theory

Helmholtz does not clearly state how his outflowing command signals are supposed to produce stability. Since stability depends upon the eyes in fact moving, the shift of the retinal image must be important. The term 'outflow' theory is thus misleading, for it ignores this shift of the retinal image and the information it transmits. Passive eye movements produce marked contrary shifts of the visual world: Helmholtz's theory requires these movement signals in conjunction with his command signals to produce stabilization, and this should be stated explicitly. The 'outflow' theory may, in this form, be called the 'cancellation' theory, where signals from the eye/head system are supposed to be cancelled out by signals from the image/retina system. This is similar to the view put forward by von Holst[8], but is really a natural extension of Helmholtz's theory.

Mackay[4] has recently made the interesting suggestion that stabilization is not something which is achieved, but rather that things are regarded as stable unless there is sufficient evidence to the contrary. Thus he says: "what requires informational justification is not the maintenance of stability but the perception of change", and also: "the retinal changes resulting from voluntary movement evoke no perception of world-motion, because they are not an awkward consequence to be compensated, but part of the goal to be achieved". He explains the apparent movement of the perceptual world when the eye movements are paralysed by saying that the 'goal' (which is internal and conceptual) shifts with changing expectations. This may be contrasted with the cancellation of the command signals by retinal movement information.

On the 'cancellation' theory the world moves if the eye movement is thwarted because the command signal is not cancelled by the image/retina system, there being no signal. Similarly, after-images move during voluntary eye movements, because there is no shift of the image across the retina to give an image/retina signal.

On the 'cancellation' theory we may predict that if we could destroy movement information in the image/retina system then the visual world should seem to move with the eye during voluntary eye movements. This may be done simply by illuminating the field with a stroboscope set to 4–5 flashes/sec. Movement is then only seen when the eye follows an object. With the eyes stationary, a moving object is observed to occupy successive positions, but not to move. When it is tracked it does, however, in stroboscopic illumination, appear to move. Voluntary eye movements produce loss of stability; the entire visual field moves in jerks. If now smooth eye movements are produced, by tracking a small self-luminous object held rather close to the eye, the entire visual world may be seen to move with the tracking object, and therefore with the eyes. This is observed best with a faintly glowing filament mounted on a pendulum bob; the visual world then swings with the bob, provided the distance and velocity conditions are appropriate.

This is difficult to reconcile with Mackay's 'null hypothesis' view of the matter, for the expectation of movement can scarcely be supposed to be related to the manner of illumination or to the kind of movement of the eye.

Mackay's observation that a stationary glowing filament moves though the stroboscopically lit field remains relatively stable during passive eye movements would be expected on the 'cancellation' hypothesis, for the image/retina system should give movement information from the self-luminous filament only, and the eye/head system will give no information. The new observation given here, that the visual world moves with the eyes under these conditions when following a target, seems to be positive evidence for the cancellation hypothesis.

It may be suggested that saccadic movements are important in providing large movement signals which may be readily computed to give cancellation.

I wish to thank Prof. O. L. Zangwill for much advice and encouragement, and for most generous help in writing this article. I have benefited by discussions with P. E. K. Donaldson, R. Warren, A. J. Watson, F. Campbell and other colleagues. Miss Jean Wallace gave valuable help testing subjects; the Medical Research Council provided a maintenance grant for Miss Wallace and a grant for apparatus.

BETA-PROPIOLACTONE AS A TOXOIDING AGENT

By E. S. ORLANS
Department of Animal Pathology, University of Cambridge

AND

V. E. JONES
Bayer Biological Institute, Newmarket, Suffolk

THE conversion of a bacterial exotoxin into a non-toxic antigen suitable for injection into animals presents special difficulties in the case of an unstable substance such as the β-toxin of *Cl. welchii* Types *B* and *C*. This antigen, which is used for vaccinating domestic animals against enterotoxæmia, deteriorates rapidly[1,2], even at 4° C.

The usual method of toxoiding β-toxin for vaccine preparation involves incubating the culture filtrates with formalin at 37° C. until the material is no longer lethal for mice. Culture filtrates with initial minimum mouse lethal doses of 0·005–0·001 ml. normally require 9–21 days to become non-toxic. More concentrated solutions of β-toxin, prepared by ammonium sulphate precipitation or by freeze-drying of the culture filtrates, take proportionately longer.

The antigenic potency of these vaccines is tested in rabbits as follows: two doses of 2 ml. each of the inactivated preparations to which alum is added to a final concentration of 1·0 per cent are injected. There is an interval of four weeks between the two injections and the rabbits are bled two weeks later. The antibody contents of sera obtained in this manner from about ninety rabbits used for testing twelve batches of formalin-inactivated culture filtrate averaged 7·58 international β-antitoxin units/ml. Seventeen batches of formalin-inactivated Type *B* culture were tested by the procedure recommended in the British Veterinary Codex for Lamb Dysentery Vaccine and the antibody contents from the rabbit sera averaged 2·75 international β-antitoxin units/ml. (the minimal response for this vaccine should be 2·5 international β-antitoxin units/ml.).

A concentrated Type *C* filtrate (minimum mouse lethal dose, 0·0002 ml.) was used for comparing the toxoiding properties of β-propiolactone with that of formalin. The final concentrations of β-propiolactone used were 0·3, 0·6, 0·9 and 1·0 per cent (v/v); formalin concentrations were 0·6 and 3·0 per cent. The β-propiolactone was added as a chilled, freshly prepared 10 per cent (v/v) aqueous solution and the mixtures were buffered with 0·5 *M* disodium hydrogen phosphate. Formalin was added as a 40 per cent solution of formaldehyde without buffering. The reactions with β-propiolactone were complete after 2 hr. incubation at 37° C., when no more acid decomposition products were formed. The mixtures treated with 0·3 and 0·6 per cent β-propiolactone were still lethal to mice, but when pooled were tolerated by rabbits, with, however, some œdema. The portion of filtrate treated with 0·6 per cent formalin was still highly toxic after 8 days incubation at 37° C. and was discarded. The portion treated with 3·0 per cent formalin became non-toxic after 3 days.

The antigenicity of all the samples was tested by the procedure already described, using three rabbits for each of the β-propiolactone-treated samples and two rabbits for the formalin-treated one. The antibody response of these rabbits is shown in Table 1.

Table 1. ANTIBODY RESPONSES TO β-TOXIN TOXOIDED WITH β-PROPIOLACTONE OR FORMALIN

Treatment of β-toxin preparations	Antibody contents of rabbit sera (β-antitoxin units/ml.)
0·3 and 0·6 per cent β-propiolactone (pooled samples)	100 60 170
0·9 per cent β-propiolactone	120 50 50
1·0 per cent β-propiolactone	80 80 110
3·0 per cent formalin	4 20
0·6 per cent formalin (12 different culture filtrates)	7·58 (mean value from sera of 90 rabbits. Range 22–3)

The reactions of β-toxin, before and after treatment with β-propiolactone, with a homologous horse antiserum in agar gel are shown in Fig. 1. The continuity of the band of precipitate formed between the antiserum and the various antigens in the peripheral wells shows that the reduction in toxicity obtained by treatment with β-propiolactone was not accompanied by any alteration in the reaction of the toxoid with antibody against the original toxin.

A similar experiment was undertaken with a purified preparation of β-toxin, a more stable protein antigen[3] prepared from filtrates of *Cl. welchii* Type *D*. The toxic and immunizing properties of β-propiolactone- and formalin-treated samples were examined together with their precipitation in agar gel and flocculation by the optimum proportions method. Here again, it was found that the toxicity was reduced much more rapidly by β-propiolactone than by formalin; that, in agar gel using the homologous horse antiserum, a common band of precipitate was given by the untreated samples and those treated with β-propiolactone at concentrations up to 1·2 per cent (Fig. 2). Samples treated with less than 0·9 per cent β-propiolactone had the same flocculation rates and optima as the untreated samples; higher concentrations of β-propiolactone led to a shift of the optimum towards higher antigen concentrations. In contrast to this, formalin treatment that was just sufficient to render our ε-antigen non-toxic produced a toxoid that no longer gave recognizable flocculation zones with antiserum and the reaction of which in agar gel was markedly altered, as was also shown by Schuchardt, Munoz and Verwey[4]. However, the antibody responses of rabbits inoculated with a β-propiolactone-treated ε-toxoid were only slightly better than those obtained with a similar formalin-treated preparation.

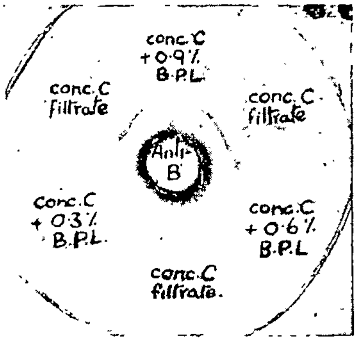

Fig. 1. Reactions of β-toxin (in a concentrated Type *C* filtrate) before and after treatment with β-propiolactone (*B.P.L.*), with Type *B* antiserum

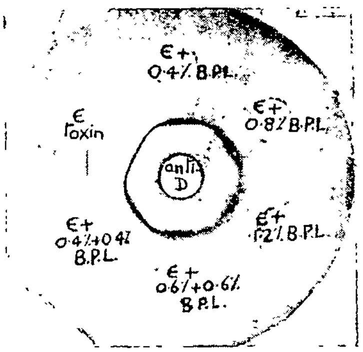

Fig. 2. Reactions of ε-toxin before and after treatment with β-propiolactone (*B.P.L.*), with Type *D* antiserum

The rapidity of the interaction of β-propiolactone with protein antigen makes it possible to avoid the prolonged incubation at 37° C. required by the formalin toxoiding process at the usual formalin concentrations, and any deterioration resulting from this. The apparent lack of change in the flocculating and agar gel precipitation behaviour of the β-propiolactone-treated toxoids indicates that β-propiolactone does not produce the changes in solubility and other side reactions (for example, cross-linking) which occur with formaldehyde. The experiments with ε-toxin, however, have shown that the preservation of these *in vitro* properties is not necessarily an index of better immunizing properties. This was also shown by Schuchardt *et al.*[4], who found that formalin-toxoided ε-preparations which no longer gave visible reactions with antitoxin still produced high antitoxin titres in sheep. The tenfold improvement in antibody response found when β-toxin is toxoided with β-propiolactone rather than formalin may be due to the inhibition of the breakdown process, probably enzymatic, which is responsible for the quick deterioration of β-toxin.

ROLE OF HYALURONIDASE IN THE RE-ABSORPTION OF WATER IN RENAL TUBULES : THE MECHANISM OF ACTION OF THE ANTIDIURETIC HORMONE

By A. G. GINETZINSKY

Institute of Evolutionary Physiology, Academy of Sciences of the U.S.S.R., Leningrad

According to recent theories the antidiuretic hormone acts by increasing the permeability of the nephron walls. As a result, hypotonic urine, following the osmotic gradient, is reabsorbed[1-3]. That the neurohypophysial hormone dilates the minute membrane pores has been demonstrated for frog skin[4]. Diuresis and antidiuresis are presumed to be due to a similar change of pore size in the membranes of the distal tubules. Yet there is no direct evidence for this suggestion; it is based on indirect information, deduction and the analogy with the tests on frog skin.

A few years ago we discovered that under certain conditions the urine of all mammals contains hyaluronidase[5]. Hyaluronidase activity depends on the extent of diuresis, dropping to zero after water loading (Fig. 1).

A special analysis has shown that the reduction of activity during high diuresis cannot be accounted for simply by dilution of the enzyme entering the nephron lumen at a fixed concentration. The experiment in which increased urine formation is effected by osmotic diuretic loading, and not by water loading, is of particular significance. As is seen from Fig. 2, the increased urine flow during osmotic diuresis is not accompanied by decreasing hyaluronidase activity.

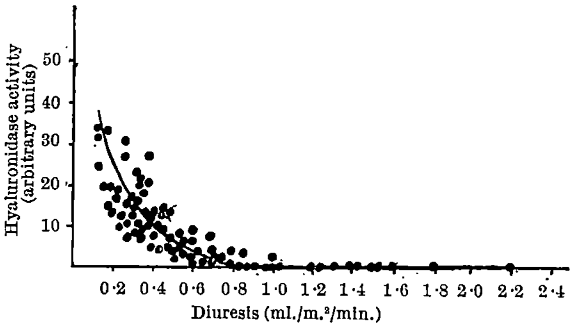

Fig. 1. Variation of diuresis with hyaluronidase activity

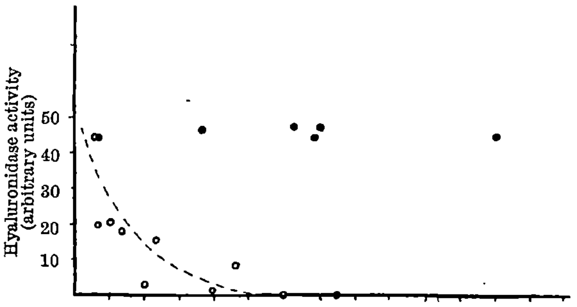

Fig. 2. ●, Osmotic diuresis; ○, water diuresis. According to experiments on the same dog

Hence we can infer that the amount of hyaluronidase in the nephron lumen is increased by neurohypophysial hormone: as the secretion of antidiuretic hormone is inhibited (water diuresis) the enzyme content in the urine drops, but it remains high when the hormone acts on the kidney (osmotic diuresis). This suggestion is supported by the following experiment.

Urea was administered to rats during complete water diuresis. As a result, urine formation increased. Pituitrin was then injected and diuresis decreased somewhat, but it remained high. Nevertheless, as is seen from Table 1, the urine acquired a considerable hyaluronidase activity[6].

Table 1

Water loading		Administration of urea		Injection of pituitrin	
diuresis (ml./mm.)	activity (arbitrary units)	diuresis (ml./mm.)	activity (arbitrary units)	diuresis (ml./mm.)	activity (arbitrary units)
1·2	0	2·5	0	1·9	11
1·5	0	5·5	0	2·2	13
1·8	0	7·0	0	1·1	11
2·8	0	6·0	0	5·5	28
2·8	0	6·0	0	2·8	31
4·5	0	6·0	0	2·8	30
4·5	0	11·0	0	2·8	16

These results led us to the conclusion that in the course of facultative re-absorption, osmotically free water leaves the lumen of the distal tubules not through the cell cytoplasm but through the intercellular cement, with hyaluronic acid as a constituent. In a state of hyperhydration of the organism, this cement is almost waterproof, which enables hypotonic urine to be formed.

During dehydration, antidiuretic hormone causes hyaluronidase secretion by the nephron cells. Under the action of the enzyme, mucopolysaccharides of the intercellular cement are depolymerized and undergo hydrolysis, the multicellular tubule membrane becoming permeable to water. By means of a direct histochemical study we have verified this suggestion[7].

White rats were used in our experiments. One group of animals was killed at the peak of water-diuresis, the other after being deprived of water for 48 hours or after pituitrin injection. The kidneys of hyperhydrated and dehydrated rats were quickly removed and studied histochemically.

On staining the kidney slices with toluidine blue, we found, in the area of the collecting ducts, structures

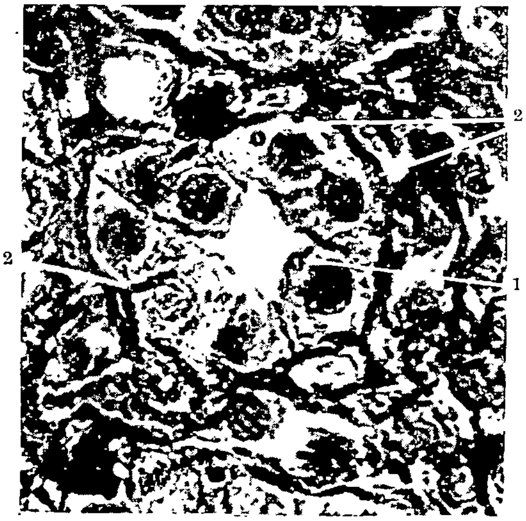

Fig. 3. The collecting duct region during water diuresis. 1, duct epithelium; 2, mucopolysaccharides in the intercellular cement and in the basement membrane; these are black on the microphotograph and stained red on the slice. (× 1,080)

showing the typical red metachromasia characteristic of hyaluronic acid. At the peak of water diuresis, the collecting duct epithelium consists of highly prismatic cells, with abundant cytoplasm and nuclei in the centre of cells (Fig. 3). Epithelial elements are cemented by intercellular layers stained red, which shows that they contain hyaluronic acid. On the photomicrograph they are seen as black lines. The basement membrane reveals a similar metachromasia which appears as clearly outlined fibres (red in the preparation and black in the photomicrograph) surrounding every duct.

This picture, typical of the kidney of a hydrated rat, changes abruptly when the animal undergoes dehydration or when pituitrin is administered (Fig. 4). The cells lose most of their cytoplasm and the nuclei project into the lumen. The reason for this change in the epithelium is the complete dissolution of the cytoplasmic apical ends into the lumen of the tubules. This loss of cytoplasm appears to be identical with apocrine secretion of the collecting duct epithelium due to antidiuretic hormone.

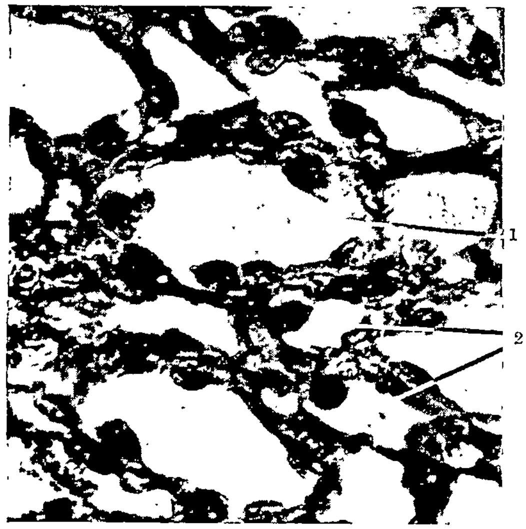

Fig. 4. The same region as Fig. 3 after pituitrin injection. The flattening of the duct epithelium is shown. Positive reaction to γ-metachromasia has given place to a diffuse pinkish background. 1, collecting ducts; 2, lymphatic capillaries. (× 1,080)

As a result of the antidiuretic hormone effect, the metachromasia of the fibres stained by toluidine blue changes, turning violet instead of red. When these changes reach their maximum, the mucopolysaccharide intercellular layers disappear completely and the hyaluronic elements of the basement membrane are no longer seen. γ-Metachromasia remains only as a diffuse homogeneous pinkish background uniformly filling in all the interstices between the ducts.

After injection of pituitrin, numerous tubules, previously unseen, appear in the meshes of the intertubular mucopolysaccharide net in the immediate vicinity of the ducts. In the cross-section of the walls of these new tubules, cells typical of the capillary endothelium are seen. There is much evidence that these tubules are lymphatic kidney capillaries which open under the influence of the antidiuretic hormone.

The processes which occur in the area of the collecting ducts as the result of natural antidiuresis brought about by continued lack of water are, in principle, similar to those that occur after injection of pituitrin.

The rapidity of morphodynamical change in the system of collecting ducts is startling: they reach a maximum 15–20 minutes after the injection of the hormone.

Water administered to dehydrated animals causes a quick reversal of all these changes. The first signs of the regeneration of hyaluronic stroma of the intercellular substance and epithelial elements appear in 20 minutes. Sixty minutes later, when intensive water diuresis sets in, the tubule structure approaches the state characteristic of the hydrated kidney. There is little doubt that the changes in kidney structure which are the morphological expression of antidiuretic hormone action underlie the antidiuretic action of the hormone.

We have arrived at the following conclusions based on these results.

1. Antidiuretic hormone stimulates the collecting duct cells, which begin to secrete apocrine-wise, hyaluronidase being a constituent of the secretion.

2. The secreted enzyme rapidly depolymerizes mucopolysaccharide complexes of the intercellular cement and the basement membrane of the tubules. This makes the structures separating the tubule lumen from the interstitial tissue permeable to water. The hypotonic fluid in the tubules then follows the osmotic gradient and undergoes facultative reabsorption.

3. The water entering the interstitial space is drained by an extensive system of newly opened lymphatic capillaries.

4. All these processes are localized in the most distal part of the nephron. It is the collecting ducts that are the main site of facultative water re-absorption. It seems reasonable to change the name 'collecting ducts' as it does not suggest the importance of the processes occurring inside the ducts.

Radio Observations of Hypersonic Shock Waves

A SHOCK tube consists essentially of two sections, one containing a gas at high pressure and separated from the test gas in the other section by means of a diaphragm. A shock wave is produced in the test gas when the diaphragm is suddenly broken. As the initial pressure ratio is increased, the shock front attains a limiting velocity $U \approx \frac{\gamma_1 + 1}{\gamma_2 - 1} a_2$, and the corresponding limiting shock Mach number is U/a_1, where a_1, a_2 are the speeds of sound and γ_1, γ_2, the specific heat ratios (C_p/C_v) of the gases in the test and high-pressure sections respectively. Thus if both sections contained the same monatomic gas for which $\gamma = C_p/C_v = 1 \cdot 67$ the limiting shock Mach number would be approximately 4. Greater shock Mach numbers could be achieved if the speed of sound in the high-pressure section were increased, for example, by using a light gas and by raising its temperature. Thus hydrogen is a suitable driver gas, and it could also be brought to a high temperature by burning oxygen in it. An alternative method of producing a high shock velocity is to introduce an intermediate section into the shock tube[1]. When the first diaphragm is broken, a shock wave is produced in the intermediate section, and the resulting column of hot gas flowing at high speed in this section then acts as the final driver to initiate a faster shock wave in the test section. In a previous communication[2] we described the radio measurement of the velocity of shock waves by means of the Doppler effect. The value of this technique, which provides detailed measurement as the shock wave travels along the tube, is illustrated by its application to the study of methods for producing hypersonic flow.

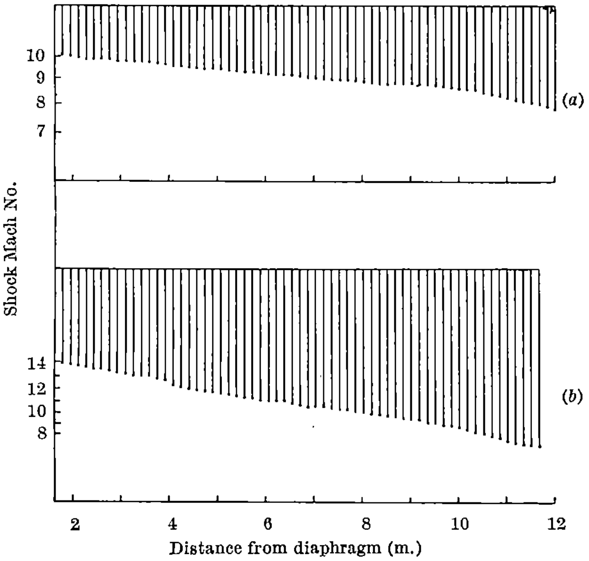

Fig. 1. Comparison of attenuation of shock waves in argon, initially at room temperature and 3·0 mm. pressure, using as driver: (*a*) hydrogen at room temperature and 32·7 atmospheres pressure; (*b*) a combustion mixture of hydrogen at 6·8 atmospheres pressure with 10 per cent oxygen

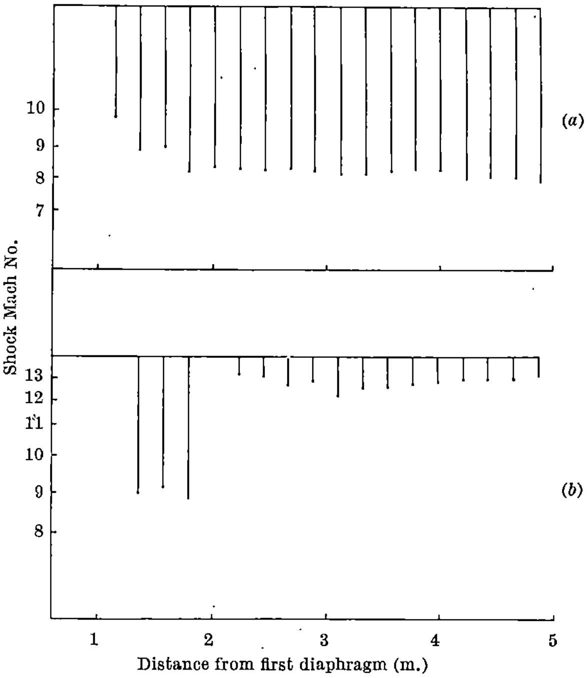

Fig. 2. Comparison of shock velocities using single and double diaphragms. The gases, initially at room temperature, and pressures as follow, are: (*a*) driver, hydrogen at 17·7 atmospheres; test section, argon at 5·0 mm.; (*b*) driver, hydrogen at 17·7 atmospheres; intermediate section, argon at 3·0 mm.; test section, air at 0·3 mm.

Attenuation is a most important consideration when a long shock tube is used to obtain a proportionately long column of flow at high Mach number. The attenuation is influenced not only by the diameter and surface construction of the walls of the tube, but also by lack of uniformity or turbulence in the action of the driver. Fig. 1 shows for comparison the shock velocities obtained in argon in a steel shock tube of internal section 5·4 cm. square using an aluminium diaphragm when the gas in the high-pressure section is (*a*) hydrogen at room temperature and (*b*) a combustion mixture of hydrogen with 10 per cent oxygen. With the cool hydrogen as driver, the shock velocity which initially corresponded to a Mach number of 10 (relative to the argon in its initial state at room temperature) fell to about Mach 8 in a distance of 10 m. When heated by combustion, the driver produced a higher initial velocity, equivalent to nearly Mach 14, but in a distance of 10 m. the Mach number had fallen to about 7. This greater attenuation is attributable to the imperfect state of the combustion mixture. Although it may be possible to improve the combustion technique, the serious attenuation shown in Fig. 1*b* occurred when a heated wire was held lengthwise down the high-pressure section to attain uniformity in the combustion process. Previous trials of multiple ignition points had proved far less satisfactory.

The experiments on the alternative method using an intermediate section were performed in a shock tube made of silver-plated brass having a circular section of internal diameter 5·1 cm. Typical results obtained in this tube with a single diaphragm of aluminium, again using hydrogen at room temperature as driver, are shown in Fig. 2*a*. Excluding the initial stages during shock formation, the velocity of the shock wave decreased only slightly during its transit along the 5-m. distance from the diaphragm to the end of the tube; the attenuation is of the same order as that shown in Fig. 1*a*, which corresponds to about 0·2 in Mach number per metre. A second diaphragm was then introduced in order to form an intermediate section. The second diaphragm is relatively weak, as it is required only to withstand the comparatively low pressure in the intermediate section and to break when the intermediate shock wave impinges on it. A suitable material is 'Melinex', a polyester film manufactured by Imperial Chemical Industries Ltd., which also has the advantage of transparency to the 6-cm. radio waves used for the Doppler system of velocity measurement. The radio probe could thus look through the second diaphragm to observe the oncoming shock in the intermediate section as well as the shock produced in the final section. Fig. 2*b* shows the results obtained using hydrogen in the high-pressure section, and argon and air in the intermediate and final sections respectively, all the gases being initially at room temperature. With the pressure ratios noted on the diagram, a Mach number of 9 was obtained in the intermediate section jumping to Mach 12 in the final section and showing no evident attenuation. These results indicate that the double-diaphragm method appears to be much more promising than the combustion method for attaining high shock velocites in the shock tube without undue attenuation.

We are indebted to M. Woolley for his help in adapting the Doppler technique to the circular-section tube.

Mode of Growth of Ice Crystals in Air and other Gases

It is widely known that the habit of ice crystals grown in air depends markedly on the temperature and excess of water vapour. This dependence was first studied by Nakaya and his collaborators and their results have been confirmed by many other investigators, but the problem of the factors determining habit remains unsolved.

The change of the ice crystal habit at water saturation vapour pressure with temperature is as follows: between 0° C. and about −3° C. ice crystals grow to thin hexagonal plates without internal design; between about −5° C. and −9° C. hexagonal prisms or columns are formed, between −10° C. and −20° C. hexagonal plates are again formed but thicker than at the higher temperature-range and with intricate design, with the frequent occurrence also of stellar forms and dendrites; and below −20° C. ice crystals grow along their principal axes in complex prismatic shapes. Marshall and Langleben[1] stated that the dependence of ice-crystal habit on temperature and supersaturation can be explained in terms of water-vapour excess over ice-saturation, whereas the experiments of Shaw and Mason[2] showed that the crystal habit is determined primarily by temperature, while the degree of supersaturation only modifies it. Kobayashi[3] came to the same conclusion as a result of experiments similar to those made by Nakaya *et al.* I have suggested[4] that the rate of diffusion of water vapour in air and the thermal conductivity of air play important parts in determining the mode of growth, and consequently that ice crystals should grow in different modes in air at a low pressure and in gases into which water vapour diffuses at different rates.

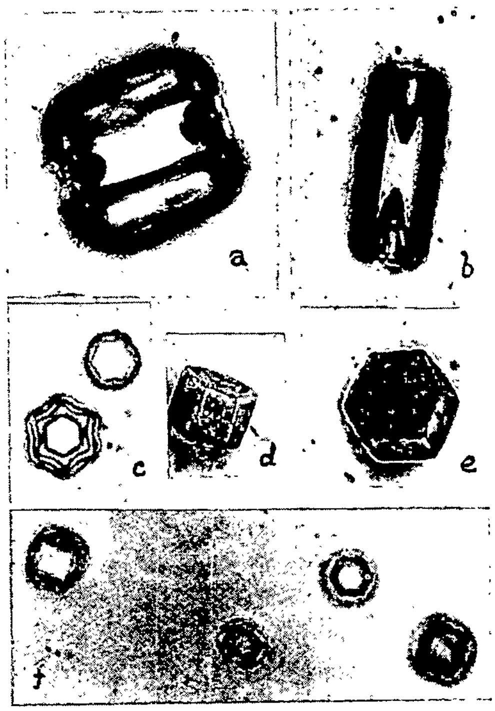

Fig. 1. Ice crystals grown in gases saturated with water vapour (×700). (*a*) Hydrogen at −7° C., (*b*) carbon dioxide at −7° C., (*c*) air at normal pressure at −16° C., (*d*) and (*e*) air at low pressure (40 mm. mercury) and at −16° C., (*f*) hydrogen at −16° C.

Experiments were therefore carried out on the growth of ice crystals in air at a low pressure and in various gases at temperatures of about −7° C. and −16° C. at water saturation; as is well known, between these temperatures a marked change in the growth habit of ice crystals is observed in air at normal pressure, since ice crystals grow preferentially along their principal axes in columnar form at −7° C. and along their lateral axes in plate-like or stellar forms at −16° C.; skeletal structures develop at both temperatures in air.

My experiments involved seeding a supercooled water cloud with silver iodide smoke in a cold chamber. In an atmosphere of hydrogen at normal pressure and in air at low pressures (80–20 mm. mercury) ice crystals grew in similar modes at −7° C. and at −16° C. which were very different from those in which they grew in air at normal pressure; in the former cases they grew to short and thick columns and skeletal structures did not develop in them. This tendency was more easily observed in air at low pressure than in hydrogen (Fig. 1). The diffusion coefficients of water vapour in hydrogen and in air at the low pressures employed are respectively 3·4 times and 10 or more times as large as that in air at normal pressure. Experiments on ice crystals grown on rabbit hairs suspended in the cold chamber yielded similar results: the ice crystals grew at nearly equal rates along the principal and lateral axes at temperatures between −7° C. and −16° C.

In carbon dioxide (in which the diffusion coefficient of water vapour is 60 per cent of that in air at normal pressure) the growth habit of ice crystals was nearly the same as in air at normal pressure, but the change in habit with temperature and the development of skeletal structures were more pronounced than in the latter case.

No difference in growth habit was observed between ice crystals grown in oxygen, nitrogen and air at normal pressure. The fact that ice crystals grow in nearly the same mode in hydrogen and in air at low pressure, excludes the possibility that the difference in thermal conductivity at normal pressure between hydrogen and air might give rise to the difference in habit, for the thermal conductivity of hydrogen is much greater than that of air at low pressure (80–20 mm. mercury) which, in turn, is not markedly different from that of air at normal pressure. The results obtained with the gases mentioned above show that molecular adsorption of a particular gas, hydrogen or oxygen or nitrogen, is not responsible for the particular mode of growth in that gas. The characteristic mode of growth of ice-crystal in hydrogen at normal pressure and in air at low pressure may be considered to be due to the high rate of diffusion of water vapour through the gases.

The High-Energy Proton Beam as a Neurosurgical Tool

Irradiation with high-energy heavy particles is suitable for the destruction of small selected regions in the central nervous system. Tobias *et al.*[1] irradiated the hypophysis of animals and man with 190-MeV. deuterons and 340-MeV. protons. Anderson *et al.*[2] made lesions in the hypothalamus of the rat using 190-MeV. deuterons. Malis *et al.*[3], making use of the thin ionization peak at the end of the beam, produced lesions at a depth of 0·8 mm. in the cerebral cortex of the cat with 10-MeV. protons. The continuation of animal experiments and the possible application of heavy-particle beams to stereotaxic radiosurgery in man[4,5] make it essential to know their effects on the central nervous system in detail.

A summary of work of the past two years is given, showing that with high-energy protons a sharply delimited lesion can be made at any desired site in the central nervous system. In the experiments some 50 rabbits and 5 goats were used. Only lesions observed up to 2 months after irradiation are considered here.

Irradiation was performed by a 185-MeV. proton beam from the 230-cm. synchrocyclotron. By focusing magnets and sweeping coils an almost parallel beam with a uniform cross-section of variable size was obtained. The desired beam profile was determined by a final aperture. The mean dose-rate was 1,000–2,000 rad per min. Dose distributions were calculated from density measurements on photographic films exposed in a water phantom and calibrated in terms of relative dose.

Transection of the spinal cord. Beams 1·5 and 10 mm. broad were directed across the spinal cord of rabbits. Lesions appeared following doses of 40,000 and 20,000 rad on the third and ninth day respectively. The lesion was sharply defined and in the white matter had the same width as the beam; it was slightly narrower in the grey matter. The changes after irradiation with the 1·5-mm. beam consisted of necrosis of nerve cells, axons, myelin sheaths and glial cells. Small perivenous hæmorrhages were present at the margin of the lesions and occasionally in the centre. A week after the onset of paresis, gitter cells and some glial cells containing iron were seen at the edge of the necrosis, and within 2–3 weeks large numbers of gitter cells were observed in sharply demarcated cystic spaces in the white matter. Slight proliferation of astrocytes occurred around the lesion. Using a 10-mm. beam the tissue reactions were more severe. There were multiple and sometimes rather large hæmorrhages as early as 3 days after irradiation. The results are reported by Larsson *et al.*[6].

Transverse lesion of the cerebral hemispheres. A beam 1·5 mm. broad was directed transversely through the upper part of the frontal lobes of rabbits. The dose was 20,000 rad. The rabbits remained in good condition and were functionally unaffected. The earliest lesions observed, 14 days after irradiation, and the changes between 2 and 8 weeks were similar. Corresponding to the path of the beam, a groove 2 mm. wide appeared on the upper surface of the hemispheres, and beneath it, in both the grey and white matter, a sharply defined narrow band of discoloration was seen. Within the lesion (Fig. 1) necrosis of nerve cells, myelin sheaths and axons occurred. Minute hæmorrhages were present in the damaged tissue, particularly in the grey matter. Collections of gitter cells were seen in the necrotic zone and around it proliferation of astrocytes.

Restricted lesion in the depth of the brain. Lesions were produced in the internal capsule of the goat

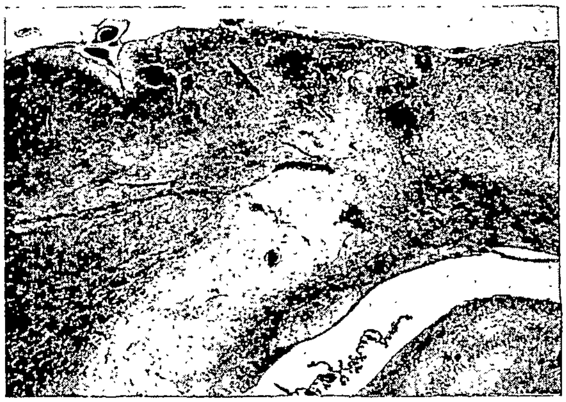

Fig. 1. Lesion of a rabbit's brain 2 weeks after irradiation with a proton beam 1·5 mm. broad. Dose, 20,000 rad. Small hæmorrhages occur in the damaged tissue, particularly in the grey matter. Azan. (× 8)

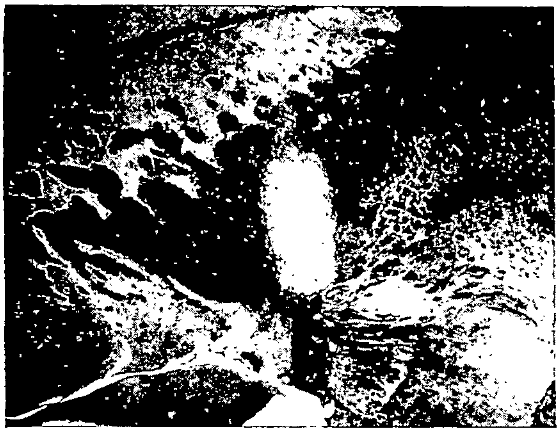

Fig. 2. Lesion in the internal capsule of a goat's brain 7 weeks after multiple port irradiation with a proton beam 2 mm. × 7 mm. Dose, 20,000 rad. Note the sharp demarcation of the lesion. Gros-Thionin. (× 4)

by the stereotaxic method[7], using multiple-port irradiation. A beam 2 mm. × 7 mm. or 2 mm. × 10 mm. and 20–22 fields were used, giving a dose of 20,000 rad at the desired site. The animals remained in good condition. Examined 4 and 7 weeks after irradiation, they presented restricted lesions in the selected areas (Fig. 2). The damaged region was lentiform and about 3 mm. × 7–10 mm. × 13–16 mm. The myelin sheaths, axons and glial cells within the lesion were completely destroyed. Slight cellular reaction was seen around some vessels at the periphery of the lesion. No hæmorrhages were seen in or around the necrotic zone, and there was no marked proliferation of astrocytes in the neighbourhood of the destroyed tissue.

With a narrow proton beam it is therefore possible to produce sharply delimited lesions of a desired site in any region of choice in the central nervous system. It must be stressed, however, that the observations apply only to lesions in their relatively early stages. The method is convenient for animal experiments.

To what extent such procedures may be used in operations on man depends on the late changes following high doses of proton radiation. Work in progress will demonstrate the long-term effects of such irradiation on the brain.

A New Approach to the Investigation of the Cause of Moisture Expansion of Ceramic Bodies

ALTHOUGH moisture expansion of ceramic bodies has been studied by many investigators its cause is still not known with certainty. The hydratable materials that play a part may be anhydrous clay minerals[1,2], γ-alumina[3], amorphous silica (silica gel)[4,5], alumino-silicic acid gel[5] and permutites, zeolites or glass[1–3,6,7]. These are all amorphous (or poorly crystalline) materials that might be expected to appear at some stage in the firing of a clay body. In the past, studies on natural materials have been complicated by complex mineralogy and/or the presence of impurities, and it has been difficult to assess the influence of each component on moisture expansion. To overcome this we have studied moisture expansion using pure co-precipitated and mixed gels of silica and alumina and some to which an impurity of sodium oxide has been added. The work forms part of an investigation into the nature and cause of the permanent moisture expansion of ceramic bodies being carried out in this Division.

The moisture expansions produced by autoclaving fired test pieces of co-precipitated gels in saturated steam at 200° C. until expansion ceased are illustrated in Fig. 1. On firing to low temperatures pure alumina gel has a high moisture expansion due to the rehydration of γ-alumina to boehmite. At high temperatures of firing the alumina gel is transformed into α-alumina, which is moisture stable. Pure silica gel shows a moisture expansion at all temperatures of firing, but this drops as cristobalite forms. All moisture expansion curves show minima at the composition of mullite, but for low temperatures of firing the formation of mullite is not complete and an appreciable moisture expansion results from the presence of unreacted alumina and silica gels. Between the composition of mullite and pure silica gel the moisture expansion curves pass through maxima which are near the composition of kaolinite and which fall as the

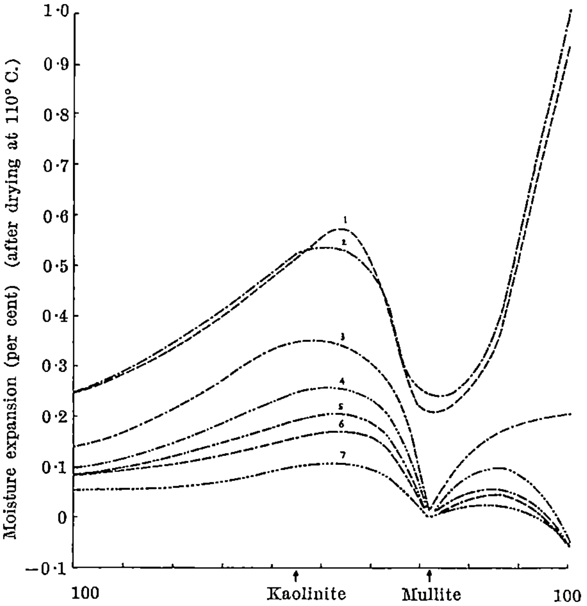

Fig. 1. Moisture expansion of co-precipitated gels of silica and alumina fired at temperatures: (1) 850°; (2) 900°; (3) 950°; (4) 1,000°; (5) 1,050°; (6) 1,100°; (7) 1,200° C.

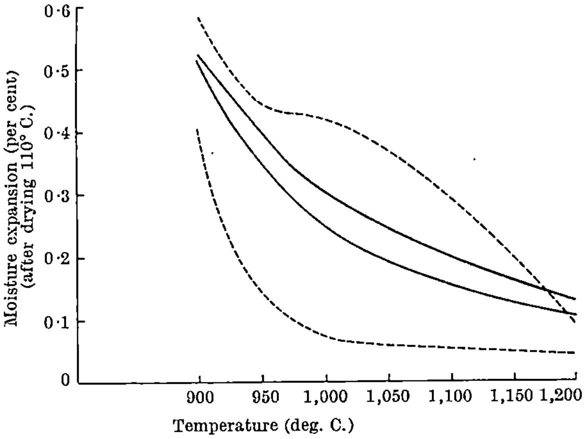

Fig. 2. Moisture expansion of pure and impure (addition of 2 per cent sodium oxide) gels with silica/alumina ratios of 2 formed by (1) co-precipitation and (2) mixing of the two components and fired at temperatures between 900–1,200° C. Top to bottom: mixed gel and sodium oxide; co-precipitated gel and sodium oxide; co-precipitated gel; mixed gel

firing temperature is increased. The only crystalline phase in this region is mullite, but there is much amorphous matter present which may be likened to Holdridge's alumino-silicic acid gel[5]. Between the composition of mullite and pure alumina gel the moisture expansion curves show a second series of maxima. These are considered to be due to the rehydration of γ-alumina to boehmite since the presence of silica prevents the formation of α-alumina even at a firing temperature of 1,200° C.

Particularly significant results are obtained by studying the moisture expansion after firing of pure and impure (addition of 2 per cent sodium oxide) gels with silica/alumina ratios of 2 (the composition of kaolinite) formed (1) by co-precipitation, (2) by mixing wet precipitated gels of the two components. The moisture expansion curves for the co-precipitated gels (Fig. 2) show that the addition of the alkali has only a slight effect, whereas in the cases of the mixed gel it has a pronounced effect and produces a curve resembling that for natural kaolinites[1,2]. This indicates that under conditions of incomplete mullitization, which exist in the mixed gels, the residual silica and alumina have reacted with soda to form a sodium alumino-silicate with swelling properties, as has been suggested for fired kaolinites[1-3,6]. However, it is doubtful if this material should be termed permutite or zeolite, since there are indications from fired kaolinites[2,3] that it possesses a low exchange capacity.

X-ray examination provides further important data on the sodium alumino-silicate. The samples of the mixed gel contain amorphous matter, γ-alumina and mullite at low firing temperatures, but at about 1,000° C. γ-alumina passes into α-alumina and at about 1,150° C. amorphous matter passes into cristobalite. Any change in structure induced by autoclaving is not revealed by X-ray examination. However, in the mixed gel with soda the cristobalite has an expanded lattice (of the order of 4 per cent volume increase) compared with that formed from the soda-free mixed gel and from pure amorphous silica.

The expanded cristobalite is probably to be considered as the β-form, metastable at room temperature, since it showed no inversion when heated. Cristobalite with similar properties has been found in opal[8] and Fuller's earth[9]. Buerger[10] suggested that the failure of the β-form to invert on cooling may be due to very small crystal size, whereas Flörke[9] considered it due to the existence of disordered forms arising from irregular stacking sequences of Si-O tetrahedral layers. We consider that it is due to the substitution of some Al^{3+} for Si^{4+} in the tetrahedral framework with the balance of charge maintained by Na^{+} held in cavities of the structure. On this hypothesis, and because the moisture expansion drops as cristobalite crystallizes, it is reasonable to conclude that the precursor to the cristobalite is an amorphous sodium alumino-silicate produced from amorphous silica, γ-alumina and sodium oxide on firing at about 1,000° C. It thus seems correct to ascribe to this amorphous compound the rise in moisture expansion in the region 1,000–1,150° C. for the mixed gel to which soda was added, for kaolinite[1,2] and, within limits, for kaolinite to which additions have been made[2,3].

Moisture expansion of low-burnt ceramic bodies can be due to the rehydration of anhydrous clay minerals[1] and that of high-burnt bodies to the rehydration of glass[7]. Our results demonstrate that amorphous alumino-silicates, amorphous silica and γ-alumina can also play important parts, depending upon the composition of the body and the firing temperature.

A fuller account of these results is to be published elsewhere.

Effect of Temperature on the Structure of Set Gypsum Plaster

VARIATIONS within the normal range of temperature do not exert a very profound effect upon the rate of hydration of gypsum plaster[1,2]. For example, Fig. 1 shows the maximum rate of increase of temperature and the induction period (defined as the time required for the rate of increase of temperature to reach 0·1° C. per min.) plotted against initial temperature for a commercial plaster consisting predominantly of the so-called hemi-hydrate of calcium sulphate. The plaster had been allowed to age until it gave steady results. The reactions were carried out in a Dewar flask so that the increase in temperature is a valid parameter of the reaction. It is seen that the induction period is constant from 0° to 40° C., above which temperature it increases gradually. The maximum rate reaches a feeble maximum at about

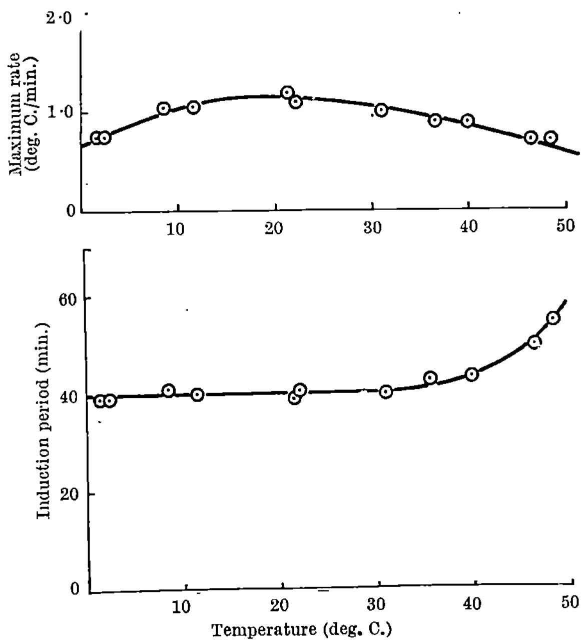

Fig. 1. The maximum rate of increase of temperature and the induction period plotted against initial temperature for a mixture of 100 gm. plaster in 60 ml. water

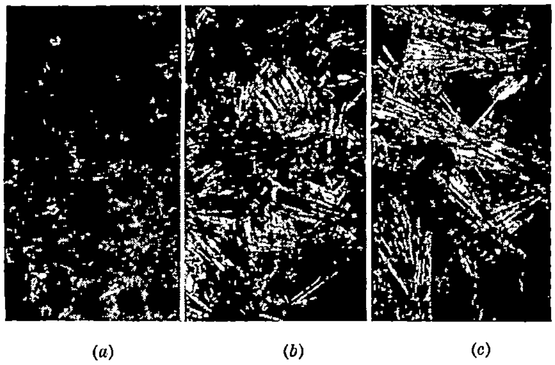
25° C. It appears, however, that at higher temperatures the rate of hydration does drop considerably[3]. Results similar to those shown in Fig. 1 were obtained for another plaster from a different source.

I have developed a method for examining the structure of set plaster under the microscope[4], and Fig. 2 shows the structures developed by a mixture of 100 gm. of plaster in 60 ml. water when setting took place at 0°, 20° and 46° C. The plaster belonged to the batch the kinetic characteristics of which are shown in Fig. 1, and it is seen that, despite the comparatively feeble effect on the rate of the setting process, temperature exerts a profound effect on the structure after setting has taken place. The differences are so great that the material produced at one temperature cannot be recognized from its appearance when prepared at another temperature. At 46° C. a sheaf-like habit predominates, whereas at 20° C. swallow-tail twins and an acicular habit are the rule. At 0° C., a fine structure which could not be fully resolved was obtained. Examination by X-rays showed that in no case was any material other than well-crystallized gypsum present in detectable quantities. The grain sizes of the specimens cast at the three different temperatures (Fig. 2) show that not only does the habit of the gypsum change as the temperature is raised but also that the number of effective nuclei decreases. It is also evident that the average pore size becomes much larger. Similar results were obtained for six commercial plasters representing gypsum deposits in four States of the Commonwealth of Australia.



(a) (b) (c)

Fig. 2. The structure developed in a mixture of 100 gm. of plaster in 60 ml. water set at various temperatures: (a) 0°; (b) 20°; (c) 46° C.

The extreme members of the series shown in Fig. 2 refer to conditions outside the range of experience in the plaster industry. However, further work has revealed that the type of structure shown in Fig. 2*a* may extend to about 10° C. or even higher, and that the high-temperature type is dominant at 30° C. In fact, a considerable variation of structure is possible over the range of practical working temperatures.

It is expected that changes in structure will be associated with changes in other properties. Preliminary experiments confirm that the breaking strength is appreciably affected. For example, specimens cast at 0° C. are about 12 per cent stronger[1,5] than those cast at 29° C. Work carried out in this Division indicates that structural changes of this type may be associated with changes in the adhesion of paint films (Hoffmann and Ridge, unpublished results) and in the expansion on setting.

It is suggested that the properties of plaster after setting may be more dependent upon temperature than was previously thought, and that some of the sporadic problems of the plaster industries, such as the 'crazing' of fibrous plaster sheets, may be associated with unusual conditions of temperature at the time of casting.

This investigation forms part of the programme of work carried out within the Division of Building Research and sponsored by the Associated Fibrous Plaster Manufacturers of Australia.

Thanks are due to Dr. W. F. Cole for the X-ray diffraction patterns.

A New Method for obtaining Thin Plane Parallel Sections of Mineralized Specimens

Nowadays a number of micro-methods (for example, X-ray and interference microscopy, and isotope techniques) are used for quantitative analyses of mineralized biological tissues. These methods have a resolution which allows analyses at or below the cellular scale. Difficulties in preparing the biological material have so far been a limiting factor in the application of the methods. An ideal specimen is a thin, plane parallel tissue section with a known thickness within the region 10–100μ. In order to prepare such sections, blocks are generally ground down to a desirable thickness, but all such methods so far used possess serious disadvantages: they do not allow a continuous control of the thickness during the grinding procedure, and wedge-shaped sections or fragments of sections are often obtained. These difficulties prompted us to seek a method for preparing ground sections based on lapping technique.

Mineralized tissue embedded in methyl methacrylate is used. The specimens are sawn into sections 3–4 mm. thick. One side of the section is lapped against cast-iron using very fine diamond abrasive, which gives the surface an extremely good quality with regard to both planarity and surface finish.

For the subsequent steps of the lapping procedure a small steel cylinder is used as a fixture for the specimen. A square-ruled area is etched on one of the plane surfaces of the cylinder, which are perpendicular to its axis. The etched lines are a few microns deep and have a width of about 50μ. On top of the etched area the lapped surface of the specimen is attached with the aid of a glue which is easy to work out to a thin film less than 0·5μ thick. When the glue is dry the specimen is cooled and ground by hand against an ordinary emery plate, down to about 1 mm. thickness.

The next step comprises grinding against a fine-grained diamond plate. The fixture is moved by hand in a V-shaped prism which is oriented perpendicularly to the rotating plane of the grinding plate. At this stage, a section of about 100μ is obtained within a few minutes. The shape of the fixture allows continuous approximate measurements of the specimen with the aid of an ordinary micrometer.

In the last step the specimen is lapped against a cast-iron plate using fine-grained diamond abrasive, the fixture being oriented with its longitudinal axis perpendicular to the lapping plane. The sections are lapped by hand to the desired thickness, checked by repeated measurements. A coarse control of the thickness of about ± 2μ can be obtained with the aid of a good micrometer. A more accurate control of thickness can be achieved with the aid of a 'microkator' (a Swedish mechanical measuring instrument, manufactured by C. E. Johansson). A complete topographical thickness-measurement, with the same lateral resolution as the light microscope can be obtained with the aid of a mechanical-optical instrument designed by Hallén[1].

Good sections have been obtained with our prototype equipment. For example, thickness measurements of a cross-section 17μ thick of the crown of a tooth was made. The thickness was measured at 100 arbitrarily distributed points within the dentin as well as the enamel. The mean thickness was 16·7μ, standard error 1·7, which gives a coefficient of variation of 10·3 per cent. The section is slightly wedge-shaped with a slope of 1/5,000.

A more detailed report will be published elsewhere.

Anodic Reactions of Mercury with Halide Ions in Dimethylformamide

DIMETHYLFORMAMIDE and other organic solvents are being increasingly used for the polarography of organic substances and inorganic ions. It has been shown that a mercury pool anode in halide solutions in dimethylformamide provides a stable reference potential[1] and that this potential (and that of similar electrodes in other organic solvents[2]) differs considerably (by about − 0·5 V.) from that of the aqueous calomel electrode[1]. We have therefore studied the behaviour of iodide and chloride ion at the dropping mercury electrode in dimethylformamide in order to identify the anode reaction and ascertain why it maintains the pool at a stable potential. The results make it clear that some familiar aspects of the solution chemistry of mercury are changed when dimethylformamide is used as solvent.

We find that tetraethylammonium iodide in 0·1 *M* lithium perchlorate in dimethylformamide gives two reversible anodic waves ($E_{1/2}$ − 0·32 and + 0·10 at 20° C. at 1·96 m*M* concentration versus saturated calomel electrode; $i_d/cm^{2/3}t^{1/6}$, 1·24 and 0·50). Progressive addition of mercuric perchlorate made first one and then the other wave cathodic, with no significant change of other characteristics. Following the methods used by Kolthoff and Miller[3] in their study of mercury complexes in water we assumed the electrode reaction of the more negative wave to be:

$$\mathrm{Hg} + a\mathrm{X}' \rightleftharpoons \mathrm{HgX}^{(a-2)-} + 2\varepsilon \qquad (1)$$

for which the potential of the dropping electrode would be given by:

$$E_{de} = \text{const.} + \frac{RT}{2F} \ln \frac{i}{(i_d - i)^a} \qquad (2)$$

We plotted E_{de} for the more negative wave against the logarithmic function of equation (2) for various values of the exponent a. If one takes $a = 4$ a good straight line of slope 0·029 (= $2{\cdot}303RT/2F$) results; the electrode reaction is therefore:

$$\mathrm{Hg} + 4\mathrm{I}' \rightleftharpoons \mathrm{HgI}'' + 2\varepsilon \qquad (3)$$

When 0·1 *N* tetraethylammonium iodide is used as the supporting electrolyte in polarography in dimethylformamide the galvanometer zero is at − 0·55 V. versus standard calomel electrode; hence one is limited to the study of substances of half-wave potential more negative than this, since at less-negative potentials the mercury micro-electrode dissolves, according to equation (3). Similarly, when a diffusion current passes through the cell owing to reduction of a substance in the solution, the same reaction must occur on the mercury pool if this is used as anode. We suggest that the stability of the pool potential is to be accounted for by supposing that complex formation maintains a concentration of mercury ions in solution sufficiently high to ensure that further quantities, produced by electrolysis, do not increase the total concentration by a significant fraction. It should be borne in mind that the overall stability constant of the complex ion is high[4], and that there is a large and constant excess of iodide ions (the stability constants of the halide complexes in dimethylformamide, which we have estimated from polarographic data, will be reported elsewhere).

We do not discuss here the nature of the more positive wave given by iodide ion, because it is not relevant to the behaviour of the anode in polarography in iodide as supporting electrolyte.

The chloride ion (as lithium chloride) behaves similarly to iodide ($E_{1/2}$, $-0{\cdot}17$ and $+0{\cdot}125$ V. versus standard calomel electrode in 4·97 m*M* solution; $i_d/cm^{2/3}t^{1/6}$, 1·16, 0·53). Here, however, there is evidence that as well as $HgCl_4''$ another complex of mercury, with a lower ratio of halogen to metal, is formed to some extent. We have also observed that in dimethylformamide the precipitation of calomel on addition of mercury to a solution of mercuric chloride:

$$Hg + HgCl_2 = Hg_2Cl_2$$

is prevented by the presence of chloride ion (in water, precipitation does occur even if chloride is present). Moreover, calomel slowly dissolves in a dimethylformamide solution of lithium chloride (but not if the chloride is absent). It is clear, therefore, that a mercury pool in chloride solution cannot be in effect a calomel electrode as it is in aqueous chloride solutions. In fact we have found[1] that a 'calomel electrode' made up in dimethylformamide with 2 *N* lithium chloride has initially a potential close to that of the saturated aqueous calomel electrode, but the potential is not stable, owing no doubt to the slow dissolution of the calomel.

A Theoretical Expression for Solubility Product

In view of the great importance of the 'solubility product' in chemistry, it was considered desirable to obtain a theoretical expression, to explain the observations described in a previous communication[1] and also to correlate the solubility product with some significant properties of the ions which combine to form the precipitates.

When two dilute aqueous solutions of electrolytes (for example, barium chloride and potassium sulphate) are mixed, the oppositely charged ions (Ba^{2+} and SO_4^{2-}) are brought into close association owing to electrical attraction and combine to form molecules of the precipitate (barium sulphate). The attraction is caused partly by Coulomb forces and partly by the mutual polarization of ions (ion–dipole interactions). The potential energy of a system consisting of oppositely charged ions is thus:

$$U = \left\{ -\frac{(z_+\varepsilon).(z_-\varepsilon)}{R_0}\left(1 - \frac{1}{n}\right) - \frac{\alpha_a(z_+\varepsilon)^2 + \alpha_c(z_-\varepsilon)^2}{2R_0^4} \right\} \quad (1)$$

where z_+ and z_- are valencies of the cation and anion, ε is the electronic charge, α_c and α_a are polarizabilities of the positive and negative ions, R_0 the equilibrium distance between the centres of the two ions, and n, a constant (about 9) occurring in Born's repulsion-energy term.

Redispersion of these ions from the precipitate does not take place unless they possess energies exceeding E (equal to $-U$). The stronger the binding forces between the ions, the smaller is their tendency to pass out into solution as free ions, and hence the greater the insolubility of the precipitate formed.

The velocity of recombination of the oppositely charged ions in solution, which is an instantaneous process (for which the energy of activation is practically zero), is:

$$k_1.(n_{Ba^{2+}}\ n_{SO_4^{2-}}) \quad (2)$$

where $n_{Ba^{2+}}$ and $n_{SO_4^{2-}}$ are the numbers of these ions per unit volume (concentrations) and k_1 is a constant.

The velocity of the reverse process, namely, the redispersal of ions from the surface of the precipitate into solution, is:

$$k_2.A.n_0 \exp(-E/RT) \quad (3)$$

where A is area of the interface of the particles of the precipitate and n_0 is the number of pairs of ions (Ba^{2+} and SO_4^{2-}) per unit area of the surface. At equilibrium:

$$k_1.(n_{Ba^{2+}}\ n_{SO_4^{2-}}) = k_2.A.n_0.\exp(-E/RT) \quad (4)$$

But by definition $(n_{Ba^{2+}}\ n_{SO_4^{2-}}) = S_P$, the solubility product of barium sulphate. Introducing the value of E given in (1) we have:

$$S_P.\left(\frac{k_1}{k_2An_0}\right) = \exp(-E/RT) = \exp\left[-\left\{\frac{z_+z_-\varepsilon^2}{R_0}\left(I - {}_{n}\right) + \frac{\alpha_a z_+^2\varepsilon^2 + \alpha_c z_-^2\varepsilon^2}{2R_0^4}\right\}\Big/RT\right] \quad (5)$$

S_P is a constant at constant temperature if A is constant. Thus,

$$-\log_e S_P = \frac{E}{RT} + a = \left\{\frac{\alpha_a z_+^2\varepsilon^2 + \alpha_c z_-^2\varepsilon^2}{2R_0^4}\right\}\Big/RT + a \quad (6)$$

since for very small values of R_0 the first term in (1), namely $\left(\frac{z_+z_-\varepsilon^2}{R_0}\right)$, can be neglected in comparison with the second term representing the mutual ion-dipole interactions. If temperature is constant, expression (6) reduces to:

$$-\log_{10} S_P = K(\alpha_a z_+^2 + \alpha_c z_-^2) + a \quad (7)$$

(K_1 and a are constants. For compounds of similar chemical constitution R_0 is nearly constant.) We should therefore expect to obtain a straight line by plotting $-\log_{10}S_P$ against $(\alpha_a z_+^2 + \alpha_c z_-^2)$. This is in agreement with results represented graphically in Fig. 1, obtained from known values of S_P and the polarizabilities of the constituent ions.

It is known that $\alpha = r^3$ for a spherical molecule, assumed to be a perfect conductor. Applying this to ions, we have:

$$-\log_{10} S_P = K_1\left\{\frac{r_a^3 z_+^2 + r_c^3 z_-^2}{2R_0^4}\right\}\Big/RT + a \quad (8)$$

If we now compare salts which are chemically similar, having one common ion and the other ion having the same valency (T being constant), equation (7) becomes:

$$-\log_{10} S_P = K_1'\alpha + a = K_1'r^3 + a' \quad (9)$$

This explains our previous observation[1] that the most insoluble inorganic precipitates are formed from hydrated ions having the largest size (including the hydration layer). On plotting $-\log_{10}S_P$ against $1/d^3$, where d is the distance of the diffusion front of each band from the starting point of diffusion, when we examine the bands in a chromatogram produced in an agar-gel layer containing the appropriate reagents during the diffusion of the electrolytes, then

following tentative mechanism for the formaf these whiskers is suggested. During the early of corrosion an adherent carbonate scale is down by the hard water, but this is not ntly complete or repairable, since the alkalinity y falls, to stifle corrosion completely, and corrokes place at local anodic points. In stagnant n localized corrosion commonly leads to the tion of a hemispherical dome of corrosion ct over a pit. It appears that under the ce of rapidly flowing water the symmetry of rm of corrosion product is disturbed, leading formation of a hollow cylinder bent through a angle in the direction of flow. Ferrous ions, d at the anodic area at the root of the whisker, along the tube, and growth of the whisker ds at the tip, where these ions are oxidized ecipitated as iron oxide on coming into contact he aerated water. The rate of ionic diffusion

may be increased by the suction induced
rapidly flowing water at the tip.

Mayne[1] has shown that rapid oxidation of
hydroxide at a pH value greater than 5 gives g

due to the presence of the copper-to-copper linkage; (2) the polarization of the latter band is the reverse of the polarization of the former.

The present measurements indicate that cupric mono-, di- and tri-bromoacetates in dioxan have an absorption band at about 80 × 10^{13} c./s. besides an absorption band at about 40 × 10^{13} c./s., suggesting that all these compounds may contain the acetate-type binuclear molecules. The dichroism measurements, which have been carried out in the visible and ultra-violet region by Tsuchida and Kobayashi's microscopic method[2], indicate that cupric monobromoacetate monohydrate and anhydrate show absorption bands at about 40 and 80 × 10^{13} c./s. in addition to absorption bands in the far ultra-violet. Moreover, the polarization of the latter band is bound to be the reverse of the polarization of the former. These relationships bear a close resemblance to those with the cupric alkanoates, suggesting the existence of the binuclear molecules in organic solvents and in the crystalline state.

Similar characteristics have been observed in the absorption spectra of cupric di- and tri-bromoacetates. Thus the two compounds, anhydrous and hydrated, show absorption at about 40 and 80 × 10^{13} c./s., besides strong absorption in the shorter wavelength region. In addition, the polarization of the latter band is the reverse of the polarization of the former. It is certain that cupric di- and tri-bromoacetates consist of the binuclear molecules in the crystalline state and in organic solvents.

The difference between the tribromo- and trichloroacetates, as observed in the present work, may be regarded as due largely to the greater inductive effect of the bromine as compared with that of the chlorine.

Paper Chromatography of Small Amounts of Vasopressins and Oxytocins

IN work concerned with the composition and estimation of neurohypophysial hormones in the posterior pituitary, the hypothalamus and body fluids, it would be desirable to have a chromatographic procedure which permits the identification in and recovery of small amounts of the active peptides from impure extracts. It would also be useful to know whether the substituted synthetic oxytocins which have recently been prepared[1] can be distinguished by a simple chromatographic method. Taylor[2] separated oxytocin, and arginine- and lysine-vasopressin by ion-exchange chromatography on resin columns. He used du Vigneaud's highly purified peptides, and the smallest amounts applied were equivalent to 0·6 mgm. of this material. Benfey[3] purified Stehle and Fraser's[4] preparations of ox posterior pituitary hormones (200 U./mgm. pressor activity and 250 U./mgm. oxytocic activity) by paper chromatography using ninhydrin as the colour reagent. The smallest amounts of the hormone preparations used were 1 mgm. However, since only terminal amino-groups react with ninhydrin, it is obviously disadvantageous to use this reagent when attempting to visualize very small quantities of the posterior pituitary peptides. Rydon and Smith[5] have shown that micrograms of peptides of all kinds, including cyclopeptides, can be detected by chlorination followed by spraying with a starch–potassium iodide solution. Reindel and Hoppe[6] improved this procedure in two ways. First, before exposure to chlorine, they moistened the paper with a mixture of watery ethanol and acetone, which prevents background staining. Secondly, they treated the N-chloropeptides with a mixture of potassium iodide and either benzidine or *o*-tolidine in acetic acid and thereby increased the sensitivity of the method.

We used Reindel and Hoppe's modification for the ascending chromatography of synthetic oxytocin, valine-oxytocin, phenylalanine-oxytocin, arginine-vasopressin and lysine-vasopressin. Other preparations used were 'Pitressin', 'Pitocin' and 'Pituitrin' (Parke, Davis and Co.) and simple acetic acid extracts of ox, hog and rat posterior pituitary glands and hypothalami. The paper employed was Whatman No. 1, the solvent was *n*-butanol/acetic acid/water (5 : 1 : 4), the length of flow was 24–48 hr. and the experiments were done at ambient temperatures. Owing to the small amounts of peptides used (see below) some of the spots faded rapidly. All chromatograms were therefore photographed immediately after development.

Areas on parallel strips, corresponding to spots obtained from reference preparations, were extracted with Ringer–Locke solution, and the activities in the eluates estimated by bio-assay. The isolated rat uterus was used for oxytocic assays; pressor activity was assayed on the blood pressure of rats anæsthetized with urethane and treated with dibenyline.

Fig. 1*a* shows a chromatogram of highly purified arginine-vasopressin and lysine-vasopressin, which were kindly supplied by Prof. van Dyke. (Saline containing chlorobutanol and acetic acid was the solvent used by van Dyke for the vasopressins obtained from du Vigneaud for pharmacological experiments. Since the sealed ampoules were heated before refrigeration, van Dyke believes that biologically inert spots in chromatograms of arginine-vasopressin represent degradation products not necessarily present in the original material, which was highly purified but not the purest which du Vigneaud and his associates have

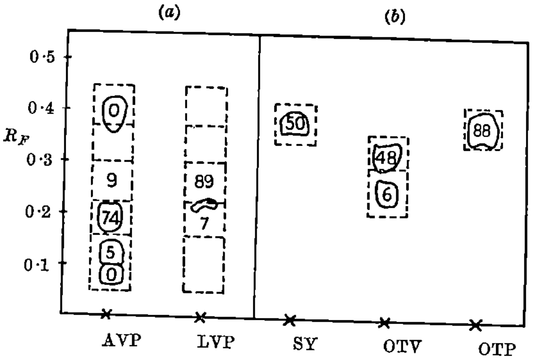

Fig. 1. Paper chromatograms of (*a*): arginine-vasopressin (AVP) and lysine-vasopressin (LVP), and (*b*): synthetic oxytocin (SY) ('Syntocinon', Sandoz), valine-oxytocin ('OTV 80', Sandoz) and phenylalanine-oxytocin ('OTP 79', Sandoz). Two strips of paper were chromatographed for each substance but only one was developed; the other was cut into pieces indicated by the broken lines. The pieces were extracted and the eluted activities were bioassayed. The figures within the columns indicate percentage recovery. The amounts (in mU.) applied at the origin *X* were: AVP, 800; LVP, 740; SY, 2,450; OTV. 300; OTP, 560

Table 1. R_F VALUES IN n-BUTANOL/ACETIC ACID OF VASOPRESSINS AND OXYTOCINS

Peptide	R_F
Arginine-vasopressin	0·19
Lysine-vasopressin	0·26
Oxytocin (synthetic)	0·37–0·40
Valine-oxytocin	0·33
Phenylalanine-oxytocin	0·37–0·39

isolated. The latter have previously commented on the instability of arginine-vasopressin.) Arginine-vasopressin gave more than one spot but the bulk of the pressor activity was found at R_F 0·19. Most of the pressor activity of ox-gland extracts was found at approximately the same R_F. In the case of lysine-vasopressin 89 per cent of the activity applied was found above the clearly stained area at R_F 0·26. Experiments with pig posterior pituitary extracts, in which larger amounts of the hormone could be applied, yielded a faint spot at the same region, which contained likewise most of the pressor activity. Valine-oxytocin (Fig. 1*b*) and 'Syntocinon' on 3 out of 6 chromatograms gave also an additional spot, which agrees with the statement of the makers that these preparations contain some inert material. Table 1 gives tentative R_F values for the active octapeptides.

The oxytocic activity of ox, pig and rat pituitary extracts was found in the same region of the chromatograms as that of synthetic oxytocin. The position of the pressor activity of rat gland extracts corresponded to that of arginine-vasopressin, which accords with the pharmacological evidence of van Dyke *et al.*[7], who found that the vasopressin of rat pituitaries behaves like arginine-vasopressin when injected intravenously into dogs. Ox hypothalamus yielded pressor and oxytocic activity at the R_F of arginine-vasopressin and synthetic oxytocin, but a marked discrepancy was noted between the colour intensity of the spots and the biological activity present in the eluates of the corresponding areas. For the present we cannot say whether this discrepancy is due to substances with a much lower potency than that of the glandular hormones or to the presence of inert material with very similar or identical R_F values as those of oxytocin and vasopressin.

Our results suggest that the colour intensity obtainable with the chromatographic procedure described varies considerably from one neurohypophysial peptide preparation to the other. For example, up to 1,500 mU. of synthetic oxytocin had to be applied to obtain a well-stainable spot, whereas 400 mU. of highly purified arginine-vasopressin (equivalent to about 0·7 μgm. of the pure peptide) were sufficient to give a spot of similar intensity. On the other hand, as little as 10 mU. (= approx. 0·02 μgm. peptide) of oxytocic or pressor activity could be eluted and assayed.

We are indebted to Prof. H. Konzett for providing the substituted oxytocins.

Complex Forms of Cellulase

RECENTLY, several articles have been published on the multiplicity of cellulase. Using paper chromatography Jermyn[1] found eight components in cellulase from *Aspergillus oryzae*, each with cellulolytic activity. Reese and Gilligan[2] found, also with chromatographic techniques, three components in *Myrothecium* cellulase, whereas Miller and Blum[3], using starch electrophoresis, found at least eight components in this product. Grimes[4] isolated from *Myrothecium* cellulase six components, of which possibly three had cellulolytic activity, and Thomas[5] found seven protein fractions by paper electrophoresis. These facts are puzzling. Whitaker[6] succeeded in isolating a homogeneous protein from crude *Myrothecium* cellulase which exhibited all the activities of the crude product, so there is a possibility that cellulase is a single enzyme. However, this has never been confirmed.

Comparing cellulase with other depolymerizing enzymes, for example, amylases and pectinases, there is a possibility that the cellulose breakdown is brought about by several discrete enzymes, a possibility which is enhanced by experiments which show that the action on cellobiose is separable from other activities[7].

That the number of discrete enzymes would in this case be as great as is indicated by the results mentioned above seems improbable.

We therefore supposed that in a crude cellulase preparation the enzyme or enzymes might be bound to a number of metabolic products, thus giving rise to a large number of complexes with cellulolytic activity.

Consequently our efforts were concentrated on the search for a method by which these bound forms of cellulase could be split up. We think we have found the first step for this purification in using a special chromatographic technique.

A crude cellulase product was obtained by growing *Myrothecium verrucaria* on a cellulose – salts medium for 14 days. Culture filtrates were concentrated in a Bartholomew evaporator, dialysed, freeze-dried, dissolved in a small amount of water, centrifuged, ultra-filtered through collodion membranes (similar to that used for dialysis) and again freeze-dried. The resulting product was a light brown powder, and normal fractionation procedures with ammonium sulphate, alcohol or acetone proved unsuccessful with respect to separation of activity and colour.

The activity of this powder was estimated, using hydrolysis of carboxy methyl cellulose as a standard.

A 50 mgm. portion was placed on top of a column of Schleicher and Schüll cellulose powder, No. 123, which had been washed previously with distilled water to which had been added sodium hydroxide to give a *p*H of 11·0 (glass electrode). The loaded column was then percolated with the same solution. The effluent was collected in 2-ml. portions in tubes which had been filled with 2 ml. of buffer at *p*H 5·6. The enzyme activity of these was determined. Two fractions were obtained, the first containing all the coloured substances, the second a perfectly colourless solution.

The specific activity of the original material was 140 cellulase units per mgm. nitrogen. Activity of fraction 1 was 70 cellulase units, that of fraction 2 was 310 cellulase units. Preliminary dry-weight measurements on fraction 2 showed a four-fold increase in activity per mgm. dry-weight, while in fraction 1 this was diminished by a factor of three. Overall losses were rather low, about 75 per cent of the original activity being recovered.

The method was very sensitive to small alterations in the conditions. At pH 5, 6, 7, 8 and 9 no separation took place. At pH 12 great losses occurred, presumably due to denaturation. Increasing ionic strength by addition of small amounts of sodium chloride up to $0 \cdot 1\mu$ also prevented the separation.

Cellulose as a carrier seems to be indispensable, identical experiments on starch columns being unsuccessful.

The question arises as to how far formation of complexes affects the activity of the free enzyme. When larger amounts have been separated, experiments will be carried out to elucidate these phenomena.

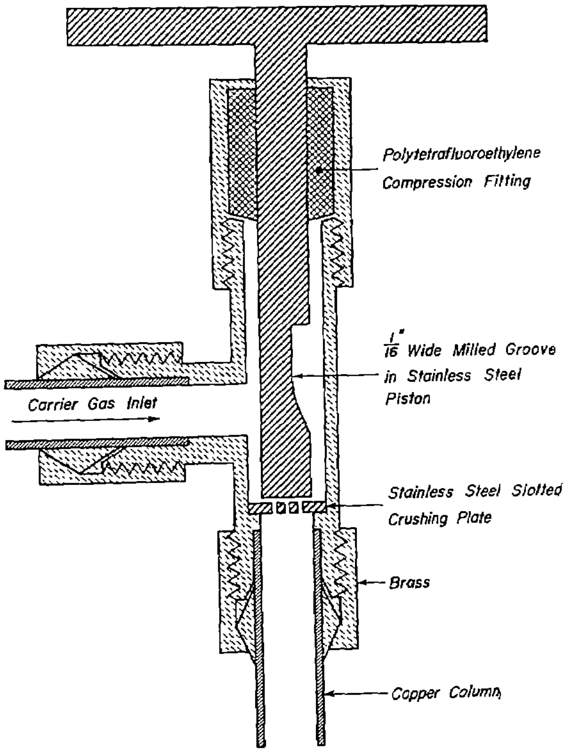
A Micro Sample Introduction System for Gas Chromatography

An ideal sample introduction system for gas chromatography suitable for use with a variety of columns and detection devices should possess the following characteristics: (1) the entire sample should be delivered to the inlet of the column as a vapour over a short time-interval to keep dilution of the sample with carrier gas at a minimum; (2) the samples delivered should be of reproducible quantity or, better, of precisely known quantity; (3) the introduction of sample should not necessitate stopping or changing the flow-rate of carrier gas; (4) the quantity of air introduced with the sample should be minimal.

With the availability of a variety of high-sensitivity detectors for gas chromatography, it has become possible to perform analyses using only a few μgm. of total sample. To take advantage of this increased sensitivity of detection, without the necessity for dilution and contamination of liquid samples with relatively large quantities of carrier liquid, an apparatus permitting the reproducible injection of known volumes in the μgm.-range was designed (Fig. 1). Samples are sealed into small glass capillaries in which the volume of liquid can be accurately measured, and introduction of the sample is achieved by crushing the capillary in the gas stream at the column inlet. There is little simultaneous injection of air, and it is not necessary to interrupt or change the flow of carrier gas at the time of introducing the sample.

The internal diameters of 1-cm. lengths of finely drawn glass capillary tubing are measured with a measuring microscope. The end of the section of tubing is applied to the surface of a liquid sample and allowed to fill partially. The capillary is shaken gently until the liquid sample occupies its central section, whereupon the ends of the capillary are sealed in a flame. The length of the column of liquid is measured with a measuring microscope and the volume of liquid then calculated. A capillary of $0 \cdot 1$ mm. internal diameter contains $7 \cdot 8 \times 10^{-6}$ cm.^{3} per mm. of length. In analyses using detection devices in which insensitivity to interruption of the flow of carrier gas permits easy access to the column inlet, the capillary may be dropped and crushed at the top of the column against a slotted plate provided for the purpose. For use with detection devices in which no interruption of the gas flow-rate is desirable, several simply constructed devices for the introduction of the capillary filled with liquid sample have been designed.



Polytetrafluoroethylene Compression Fitting
1/16" Wide Milled Groove in Stainless Steel Piston
Carrier Gas Inlet
Stainless Steel Slotted Crushing Plate
Brass
Copper Column

Fig. 1

The device consists of a vertical section of brass tubing with a side-arm, modified from a standard T-shaped copper tubing connector. A slotted plate is fixed in place over the column inlet at the lower end of the vertical section. Carrier gas enters the connector through the side-arm. A 1-cm. long groove is milled in the side of a stainless steel piston fitted into a sliding joint at the upper end of the vertical section. The joint is maintained leak-tight by means of a poly-tetrafluoroethylene compression fitting somewhat longer than the milled groove. In operation, the piston is moved upward to expose the groove above the fitting, the capillary filled with sample is placed within the groove, and the piston pushed down to its original position, with the groove in the gas stream. The capillary slides free of the piston coming to rest on the slotted metal plate below. The small quantity of air contained in the groove is permitted to pass through the column following which the capillary is crushed by the piston and the sample thus injected.

Because of the heat-resistant properties of polytetrafluoroethylene, injection of sample may be accomplished at temperatures high enough to permit rapid volatilization of the liquid. The small size of the sample reduces the size and heat capacity requirement of the surface from which rapid evaporation takes place.

Reproducibility of sample introduction was determined by comparing the calculated volumes of methyl laurate samples introduced into a chromatographic column with the response of the detector to each sample integrated with respect to time. The quotients obtained, measures of the apparent sensitivities of the detector, were reproducible to less than 10 per cent average deviation with volumes from 4×10^{-6} ml. to $0{\cdot}5 \times 10^{-3}$ ml.

Physarosterol, a New Sterol from a Slime Mould

DURING the course of isolating the yellow pigment contained in the myxomycete, *Physarum polycephalum*, a second crystalline (colourless) material was obtained from the neutral ether extracts of the tissue. Analyses showed that this substance was probably a C_{30} sterol not hitherto found in Nature. It is proposed that the compound be referred to as 'physarosterol'.

Physarosterol was isolated by separately homogenizing three different batches of tissue (15–20 gm. each) in an hydraulic homogenizer[1] with three volumes of 0·007 *M* potassium arsenate buffer[2] (*p*H 7·0). The homogenate was acidified with sulphuric acid and a one-third volume of alcohol was added. After addition of filter aid, the slurry was filtered by vacuum. The yellow filtrate was saturated with sodium chloride, filtered, and continuously extracted with ether until no more pigment was carried over into the solvent. Then the ether extract was concentrated to 100 ml. at 60° C., made alkaline with 4 *N* sodium hydroxide solution and again extracted five times with ether (separatory funnel). The aqueous phase which contained the yellow pigment was stored for later processing. The nearly colourless ether solutions were combined and allowed to evaporate slowly at room temperature. Gradually a layer of lipid formed on the top of the solution and crystals began to be deposited on the bottom of the vessel.

When crystal formation had ceased, the lipid and underlying solution were decanted and the crystals removed by filtration. Approximately 25 mgm. of sterol were obtained from 100 gm. of tissue. Recrystallization was effected twice from a minimum volume of warm alcohol–ether (1 : 2). The crystals were dendritic leaves. The following analysis was obtained: calculated for $C_{30}H_{52}O_3$: C, 78·21; H, 11·39. (Calculated for $C_{30}H_{50}O_3$: C, 78·54; H, 10·98); found: C, 78·17; H, 11·31 $[\alpha]_D^{28}$ $-55{\cdot}3°$ (*c*. 0·5 in chloroform), melting point 137–139° C. (Fischer Johns apparatus).

The compound gave an immediate digitonide precipitate and an immediate lavender colour in the Lieberman–Burchard test (eventually a green precipitate was formed). Concentrated sulphuric acid produced an intense orange colour. Physarosterol gave no colour either with tetranitromethane or with ferric chloride. A bromine solution was immediately decolorized by a solution of the sterol in glacial acetic acid. A test for alkoxy groups was negative. No carbonyl band was observed in the 260–290 mμ region of the ultra-violet (*c*. 23 mgm./10 ml. in chloroform).

The closest fitting empirical formula for physarosterol ($C_{30}H_{52}O_3$) would allow for the presence of five-ring structures. The *ABCD* rings of the cyclopentenophenanthrene nucleus would account for four of these rings. In the absence of a carbonyl group, a fifth carbocyclic or methylene dioxy ring could be excluded because the evidence for a double bond accounted for the fifth ring structure. Furthermore, since the tetranitromethane test was negative, the double bond may have been sterically hindered and endocyclic.

Two attempts were made to acetylate physarosterol by exposing it to acetic anhydride and pyridine at room temperature for 24 hr. In both experiments, the parent compound was recovered unchanged. This difficulty suggested that the hydroxy groups were in juxtaposition to tertiary carbon atoms.

In summary, these results indicated that physarosterol was a C_{30}, unsaturated, trihydroxy sterol with one of its hydroxyl groups in the 3β position.

Because the isolation of this substance is incidental to other aspects of slime mould chemistry at present being pursued, it is not anticipated that any further work will be carried out in this laboratory in regard to its structure.

I am indebted to Mr. Ralph Karler of this department for providing generous samples of *Physarum polycephalum*.

Inhibition of Pancreatic Deoxyribonuclease by Acidic Polymers

IN a recent publication the inhibition of pancreatic ribonuclease by a series of polymers possessing phenolic and carboxylic or sulphonic acid groups was compared with their action against influenza and vaccinia viruses in embryonated eggs. This communication describes the action of certain of these polymers on pancreatic deoxyribonuclease (Worthington Biochemical Corporation).

Enzyme activity was determined by the increase in optical density at 260 mμ of enzymatic digests at 29° ± 0·2° C. (Kunitz's method) in the presence or absence of graded inhibitor dilutions. The rates were computed from the linear portions of density – time graphs by the method of least mean squares, and by interpolation the inhibitor concentration reducing the rate to one-half of the control value (IC_{50}) was determined. The method permitted a reproducibility of rate measurements of ± 5 per cent in duplicate samples. While the absolute rate of the deoxyribonuclease reaction varied from day to day, this had no bearing on the IC_{50} values, which are relative figures, and were reproducible to ± 15 per cent or better. Table 1 shows the experimental conditions.

Table 1. Deoxyribonucleic acid solution (Worthington Biochemical Corporation): 400 μgm./ml. in 0·1 *M* acetate *p*H 5, 0·005 *M* magnesium sulphate, centrifuged and filtered. Deoxyribonuclease solution: 200 μgm./ml. in 0·1 *M* acetate *p*H 5

	Non-inhibited reaction (control)		Inhibited reaction	
	Blank	Digest	Blank	Digest
DNA solution	1 ml.	1 ml.	1 ml.	1 ml.
Water	4 ml.	3·5 ml.	3·5 ml.	3·0 ml.
DNase solution	—	0·5 ml.	—	0·5 ml.
Inhibitor ,,	—	—	0·5 ml.	0·5 ml.

Eighteen selected polymers were tested, representative of the following general types of polymerization: (1) phenolic carboxylic or sulphonic acids condensed with aldehydes; (2) polymers arising from the products of (1) on further condensation with phenolic acids under oxidizing conditions giving 'triphenylmethane' types; (3) oxidative polymerization of phenolic or hydroquinone-like compounds. In general, the half-inhibitory concentration for deoxyribonuclease was about three times that found for ribonuclease, under the conditions employed. The most notable exception was sodium humate from lignite, for which the ratio of IC_{50}-deoxyribonuclease to IC_{50}-ribonuclease was about 13. For the sake of comparison, heparin, sodium chitin sulphate and the polyurea from 4,4′-diaminodibenzyl-2,2′-disulphonic acid were also examined and found to agree with the above generalization, while suramin appeared to be weakly inhibitory at low, and seemingly accelerating at higher concentrations. The results for a few representative polymers are presented in Table 2. The results indicate that no noteworthy qualitative differences exist between the responses of the two nucleases to the acidic polymers investigated.

Table 2. INHIBITION OF RIBONUCLEASE AND DEOXYRIBONUCLEASE BY ACIDIC POLYMERS
(IC_{50}, half-inhibitory concentration)

Polymer	IC_{50} ribonuclease μgm./ml.	IC_{50} deoxyribonuclease μgm./ml.
Gentisic acid + CH_2O	2	4
Gentisic acid + $K_2S_2O_8$ + NH_3	3	10
(Gentisic acid + CH_2O) + HNO_2 + gentisic acid	1	3

Electron Microscope Studies of the Chemical Reactivity in Keratin Cuticle

DETAILED information about the structure of a cuticular layer of flat overlapping cells, covering animal hairs and wools, is of great technological importance. Its ratchet-like character is responsible for the greater frictional resistance to motion in the tip to root than the root to tip direction; and is one of the causes of felting.

The multilayer structure of an individual cuticle cell has been clearly established: on one hand, indirectly, from experiments involving mechanical and/or chemical fragmentation[1-5], and closely supported by some results of the work making use of high-resolution atomic replicas of wool fibres[6]; and, on the other, through a more direct method of ultrathin sectioning, combined with electron staining agents (osmium tetroxide) (refs. 7 and 8 and private communications by A. O. T. Charles and H. Mahl).

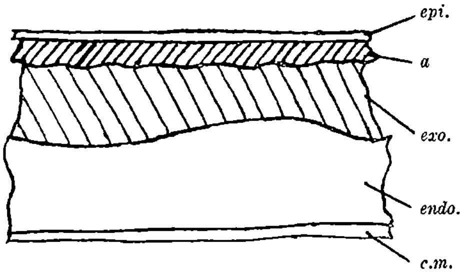

Fig. 1. Layer structure of keratin cuticle, after Lagermalm. *Epi.*, epicuticle; *a*, highly inert layer; *exo.*, exocuticle; *endo.*, endocuticle; *c.m.*, cell membrane

Thus it was concluded that immediately below the outermost thin membrane (called the 'epicuticle') there lies an easily stained thin layer (*a* in Fig. 1), resistant to both keratinolytic agents and enzyme digestion. This is followed by a keratinized layer (the 'exocuticle') which, in a fully hardened fibre, appears to show only a slight differential staining, relative to the lower cytoplasmic layer (the 'endocuticle'—insoluble in keratinolytic solvents, but attacked by enzymes), attributed to a higher concentration of sulphur in the former[8]. The character of the layer *a* is not clear; however, there can be little doubt that such a layer, if indeed present, will play an important part in determining the stability of fibres to the action of chemical agents, or such mechanical treatments as may be used to modify the frictional properties of wool in order to reduce the rate of felting.

In all these considerations an assumption was made that osmium tetroxide reacts strongly with cysteine or cystine[9]; and it occurred to us that, in order to obtain an independent confirmation of this view, use could be made of some metal salts known to form (coloured) metal sulphides in keratin[10-15].

The present investigations involved merino and Lincoln wools, mohair fibres, human hair, pig bristle and porcupine quill, which were treated either in mercury or lead salts[14,15]. In the latter case, keratin specimens were treated, for a period of up to 18 hr., in aqueous sodium plumbite solutions, at 35° C. and *p*H 11·8, at a concentration equivalent to 0·1 per cent lead nitrate[14]. Following this treatment, the specimens were washed for 12 hr., first in water at 35° C. and then in running cold water. The ultrathin sections (about 200 A. in thickness) were obtained on a commercial Philips ultra-microtome (fitted with a glass knife, 45°), using 'Araldite' as an embedding medium[16].

Fig. 2 shows the differentiation of layers in the cuticle of pig bristle, in agreement with the scheme of Fig. 1, but more clearly than in the experiments involving osmic acid (refs. 7 and 8 and private communications by A. O. T. Charles and H. Mahl). X-ray diffraction photographs of the bulk of fibres confirm the formation of lead sulphide, and there can be little doubt that the dark spots visible throughout the cross-section are related to this compound.

We are aware that some aspects of the detailed interpretation of results obtained by this method are still uncertain (such as a possibility of migration

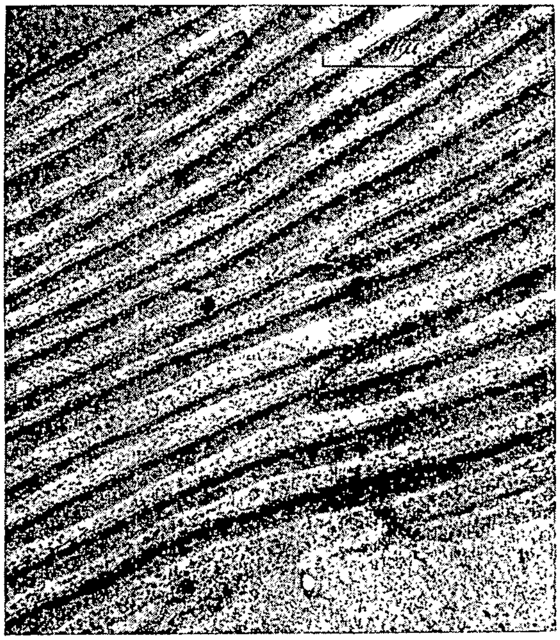

Fig. 2. An electron micrograph of a cross-section of pig bristle, after treatment in sodium plumbite. Note: the outermost cuticle cell, in top left-hand corner; and the cortex, in bottom right-hand corner. Direct print from the original (× c. 20,700)

during the formation of metal sulphides), and further experiments are in progress to clarify this and other points. Nevertheless, we believe that, even at this early stage, the workers in this and some allied fields may be interested to have their attention directed to the efficacy of our method of detecting the distribution of active groups in keratin with heavy metals, providing, thereby, a greater degree of electron contrast (though qualitatively estimated at present) than that obtained with metal atoms normally used in the practice of electron staining[17].

One of us (W. S. S.) wishes to thank the New Zealand Defence Scientific Corps for a grant which enabled this work to be carried out.

Formation of Ketones from Fatty Acids by Spores of *Penicillium roqueforti*

From time to time during the past decade attempts have been made in this laboratory to determine the mechanism by which the mould *Penicillium roqueforti* produces the flavouring and aromatic compounds characteristic of the blue-veined cheeses, Roquefort, Stilton, Gorgonzola and 'Bleu'. These aromatic compounds are a family of ketones, each one produced from a specific fatty acid which is one carbon longer, the carboxyl carbon, than the ketone. Thus the mould converts caprylic (octanoic) acid to 2-heptanone, caproic (hexanoic) acid to 2-pentanone, and so on. The overall kinetics for the conversion of fatty acids to ketones by *P. roqueforti* was published in 1955[1]; however, the individual steps in the conversion were not known. Until recently, the occurrence of the reaction under controlled conditions in the laboratory has been most erratic and unpredictable, not at all commensurate with the apparent reliability of the reaction in the manufacture of blue-veined cheese.

In attempts to study the reaction, young actively growing mould cells have always been used since, in all our work on the metabolism of filamentous fungi, such cells have much higher levels of metabolic activity. However, after a time it became apparent that the older cells were somewhat more reliable in ketone production and that the medium in which the cells were grown considerably influenced the reaction. A completely synthetic medium that provided excellent cell growth with no sporulation in submerged culture was developed[2], but mould cells grown on this medium completely lacked the ability to form 2-heptanone from octanoic acid. The formation of 2-heptanone has been used as a measure of the overall ability of the cells to form ketones from fatty acids and a chemical assay for 2-heptanone has been devised. Small amounts of corn steep liquor, protein hydrolysates and certain amino-acids when added to the synthetic medium caused the cells to sporulate, but these cells rapidly formed 2-heptanone when octanoic acid was added; it soon became evident that sporulation was a requisite for ketone formation and that the rate of ketone formation was directly proportional to the degree of sporulation. Even more surprising was the finding that it was indeed the spores that were forming the ketone and not the mycelium. Studies on the kinetics of the reaction using spores separated from the mycelium by filtration through pads of glass-wool show a direct relationship between oxygen uptake and ketone formation; all the oxygen taken up is used in ketone formation and the spores do not germinate. Spores that have been allowed to germinate or form even the smallest germ tubes cannot form ketones. Details on the kinetics and stoichiometry of the conversion of fatty acids to 2-ketones will be published elsewhere.

These findings implicate the spores of *P. roqueforti* in a series of reactions seemingly quite removed from dormancy and germination. Immediately one wonders if other mould spores, like these, might not have physiological possibilities that are now unknown or are ascribed to the vegetative cells.

Biological Potency of Eta-Tocopherol

η-Tocopherol was first isolated from rice by Green and Marcinkiewicz[1]. DL-η-Tocopherol has been synthesized by McHale *et al.*[2]. In a preliminary report to the fourth International Congress of Nutrition, Bunyan *et al.*[3] gave the potency of η-tocopherol as less than 5 per cent of α-tocopherol.

A full-scale gestation resorption assay of DL-η-tocopherol has now been completed. Virgin Norwegian hooded rats, depleted of vitamin E for five to seven months, were mated and received oral doses in equal portions on the seventh and eighth days of pregnancy, being dissected on the eighteenth day. Results from rats with less than five implantation sites were ignored and the presence of two live fœtuses was taken as the minimum positive response. Forty-five dosed rats provided the assay results, and eight undosed controls all gave negative responses. DL-η-Tocopherol was found to have 3 per cent of the potency of DL-α-tocopheryl acetate (limits of error $0{\cdot}5$–$5{\cdot}4$ per cent, $P = 0{\cdot}05$).

Differences between Duplicate Assays of Human Urinary Gonadotrophins

Sheps and Munson[1] have shown how the internal statistics of a single hormone assay may underestimate the variation actually observed on replication of that assay. Inter-assay errors may therefore be important when demonstrating qualitative differences between two hormone preparations by the simultaneous use of two different methods of assay. Such differences have been shown in human urinary gonadotrophins[2], and the errors between duplicates of the assays used have therefore been investigated.

The assays were for (*a*) total gonadotrophin, using the uterine response in immature mice, and (*b*) follicle-stimulating hormone, using the ovarian response in similar mice treated with excess human chorionic gonadotrophin[3]. Pairs of extracts obtained from human urine by the kaolin–acetone method were selected only on the grounds of availability and the fact that they had previously been assayed against one another. They were then re-assayed under the conditions described below, which were arranged so that inter-assay errors were likely to be maximal.

The coded solutions were made up by the same person but were assayed by different persons on the two occasions. In the second assay the dose-levels were designed to be as different from the original ones as was practicable. In five pairs of assays for total gonadotrophin the initial assay was calculated from quantal data and the second from the graded response. From one to seventeen months elapsed between the initial and second assays to allow for effects of storing the extracts. In assaying follicle-stimulating hormone a different batch of chorionic gonadotrophin was used in each assay of a pair.

The results of the assays using graded responses were calculated using log organ weight as the response metameter. Examination of the untransformed results pooled for each method of assay showed an obvious correlation of variance with response in both. The use of log-response stabilized variance satisfactorily in both assays, and such a transformation seems desirable in calculating the results of these assays.

Tables 1 and 2 show respectively the results of ten pairs of assays for total gonadotrophin and ten pairs for follicle-stimulating hormone. In the majority of the duplicate assays the results agree well. The fiducial limits ($P = 0{\cdot}95$) are similar in range to those which have to be used in practice[2], and in two of the twenty cases the limits of the two estimates do not overlap. These cases show significant inter-assay errors and suggest that the failure of the limits to overlap should not be used alone as evidence of significant differences between the results of two assays of a gonadotrophin. The degree of difference of the best estimates must also be taken into account and in only one case in these twenty duplicates does the ratio of the two estimates reach a value of two.

Table 1. Duplicate Assays of Total Gonadotrophin

Pair	Months between assays	Number of dose-levels		Percentage potency (95 per cent fiducial limits)		Ratio of potency estimates
		1st	2nd	1st	2nd	
1	1	2+2	2+3	72 (48–96)	92 (65–125)	1·28
2	1	2+2	2+2	348 (296–408)	238 (208–274)	1·46
3	4	2+2*	3+3	80 (49–115)	72 (53–119)	1·11
4	2	2+2	3+3	84 (56–117)	79 (43–116)	1·06
5	2	2+2	2+3	119 (70–232)	96 (74–124)	1·24
6	15	3+3*	3+3	82 (63–112)	71 (54–90)	1·15
7	15	3+3*	2+3	23 (17–31)	11 (7–15)	2·09
8	1	2+2	3+3	51 (34–72)	57 (51–69)	1·12
9	13	3+3*	2+2	114 (86–167)	100 (85–133)	1·14
10	13	3+3*	2+3	75 (52–114)	59 (35–76)	1·27

* Calculation from quantal data.

Table 2. Duplicate Assays of Follicle-Stimulating Hormone

Pair	Months between assays	Number of dose-levels		Percentage potency (95 per cent fiducial limits)		Ratio of potency estimates
		1st	2nd	1st	2nd	
11	2	2+2	2+2	292 (176–440)	154 (32–270)	1·90
12	11	2+3	3+3	27 (20–38)	29 (17–49)	1·07
13	11	2+3	2+3	17 (12–23)	9 (4–16)	1·89
14	10	2+3	2+3	986 (694–1,370)	735 (508–971)	1·34
15	12	2+3	2+2	848 (633–1,140)	877 (763–1,040)	1·03
16	1	2+3	2+3	264 (168–413)	266 (140–440)	1·01
17	4	2+2	3+3	1,620 (952–3,920)	1,810 (1,260–2,740)	1·12
18	17	2+2	2+3	67 (34–114)	95 (68–113)	1·42
19	2	3+3	3+3	15 (10–22)	15 (6–27)	1·00
20	8	2+2	3+3	2,600 (1,780–4,880)	4,800 (2,790–11,700)	1·85

The magnitude of the inter-assay error is roughly similar for the two methods. It is therefore likely that when a gonadotrophin is assayed by each method a similar error will occur between the two estimates of potency. The conditions of the present experiment were designed to accentuate inter-assay errors and a two-fold difference in estimates occurred only once in twenty pairs. If, therefore, the two methods of assay under normal conditions give estimates which show a more than two-fold difference, and the fiducial limits of which do not overlap, it is very likely that these results demonstrate a genuine qualitative difference. This is being used as a rough working principle until more precise analyses of these and similar data are available.

We are grateful to Dr. A. C. Crooke and Dr. W. R. Butt, and to other participants at the 1957 meeting of the Gonadotrophin Club for discussions on this topic. One of us (P. S. B.) is supported by the Medical Research Endowment Fund of the United Birmingham Hospitals.

Concentration in the Human Ovarian Follicular Fluid of Radioactive Tracers and Drugs circulating in the Blood

The potential hazard of genetic changes induced by radioactive substances and of mutagenic and radiomimetic action of non-radioactive compounds is of current interest. Information, however, as to the intimacy of contact of these substances, when introduced into the human body, with the reproductive cells, particularly the ovum, is scant.

It has been well established that many radioactive tracers, compounds and drugs are transferred from the vascular into other compartments of the human body. However, it is not known whether in the human these substances are transferred into the ovarian follicular fluid. Since the follicular fluid surrounds the ovum and corona radiata and the egg might depend for its nutrition on this material, a transfer of exogenous substances into the ovarian follicular fluid might bring potentially noxious material into close proximity with the ovum or, by means of the cells of the corona radiata, into actual contact with the egg.

Previous animal studies[1-5] with sulphur-35 and to a lesser extent[6] with phosphorus-32, as well as with the dyes, trypan blue[7] and Evans blue[8], have shown the appearance of all of these compounds in the ovarian follicular fluid. Thus, beta-emitting radioisotopes have already been shown in animals to accumulate in an area where they may potentially do harm. Damage to the offspring has been described when the ovaries of intact animals were briefly exposed to a carcinogenic substance[9].

Our particular interest in this problem stemmed from our observations in a related field—intravenously administered iodine-131 and sodium thiocyanate–^{35}S, were rapidly excreted with and concentrated in the human cervical mucus. Their concentrations in mucus were many-fold higher than those obtained in blood[10]. As the next step in this investigation of the accumulation of exogenous material within the human female genital tract, the possible appearance of such material in the follicular fluid was investigated.

These studies were performed in twenty-nine premenopausal women undergoing hysterectomy, the principal indications for this procedure being cystocœle, menometrorrhagia or myomata. Eight patients received two different drugs simultaneously. None showed any gross abnormality of ovarian structure or function. The ovaries were exposed during surgery and the follicular fluid aspirated by puncturing a prominent follicle with a 25-gauge hypodermic needle attached to a tuberculin syringe. A venous blood specimen was drawn simultaneously. Whenever possible, a segment of the punctured follicle was removed for histological examination. Follicular fluid and blood were examined immediately. The following materials—iodine-131, iodine-131-tagged human gamma-globulin, mercury-203-tagged mercaptomerin, carbon-14-tagged meprobamate, penicillin and 'Pyridium' were given before hysterectomy by the route and at the time-intervals indicated in Table 1.

Table 1. THE RELATIVE CONCENTRATION IN HUMAN OVARIAN FOLLICULAR FLUID AND SERUM OF RADIOACTIVE TRACERS AND DRUGS

Drug and route of administration	No. of observations	Interval at which specimen obtained (hr.)	Ratio : Follicular fluid / Serum Mean	Range

^{131}I (intravenous)	7	12–60	1·13	0·60–1·62
^{131}I-human gamma-globulin (intravenous)	6	13–21	0·45	0·09–0·81
^{203}Hg-mercaptomerin (intravenous)	3	11–12	14·18	4·20–19·70
^{14}C-meprobamate (per os)	4	2·5–11	1·03	0·59–1·40
Penicillin (intramuscular)	4	2–4·5	0·33	0–0·50

Iodine-131 and mercury-203 activity were determined by gamma counting with a well-type scintillation counter, and carbon-14 was measured by beta-assay with a windowless flow counter. Penicillin concentration was determined from the bacteriostatic activity of the samples. Qualitative tests were employed to detect the presence or absence of 'Pyridium' in the follicular fluid. The results are expressed as the ratio of the relative concentrations of the test materials in the follicular fluid and serum.

The results show that all the compounds tested, iodine-131, iodine-131–gamma-globulin, mercury-203–mercaptomerin and carbon-14–meprobamate, penetrate from the blood stream into the human ovarian follicular fluid (Table 1). The results from the studies with iodine-131 show that penetration commences within 15 min., and the results with iodine-131–gamma-globulin suggest that a large molecule can pass into the follicular fluid at a slower rate. Of particular interest is the appearance in the follicular fluid of a mercurial diuretic agent and of a tranquillizer. 200 mgm. of 'Pyridium' was given orally 3–19 hr. before puncture of the follicle in six patients; the drug was detected in the follicular fluid in every instance.

Sixteen histological preparations were obtained; six of them revealed fresh corpora lutea from which tertiary follicular fluid had been obtained. The results are not sufficiently extensive to show any difference in the concentration of substances in the fluid from normal follicles as compared with that from the young corpora lutea. Our previous observations[10] have shown, however, that the ratio for iodine-131 is very low for large pathological ovarian cysts.

The results indicate not only that administered compounds penetrate into the human ovarian follicular fluid but that they may be concentrated therein. This property might be particularly significant when exhibited by drugs with mutagenic and radiomimetic effects or with the capacity to interfere with enzyme systems of the ovum, particularly during division. It is not known whether drugs present within the follicular fluid can do harm to the ovum, especially when administered over a long period of time, or at a particular stage in its development, such as when the ovum is dividing.

These studies suggest that the human egg *in situ* within its own follicle is exposed to therapeutic agents introduced into the general circulation. We are at present attempting to determine whether such materials appearing in the ovarian follicular fluid actually penetrate into the egg proper.

We wish to express our gratitude to Dr. E. Stewart Taylor for making this study possible, to Dr. Robert Dean for obtaining the surgical specimens, and to Dr. Stuart G. Dunlop for performing the bacteriological tests.

This study was aided in part by Contract No. *AT*(11-1)-282 between the United States Atomic Energy Commission and the University of Colorado.

Effect of Nitrous Oxide on the Radiosensitivity of Mouse Ehrlich Ascites Tumour

It has been shown that inert gases at pressures higher than 1 atm. reduce the oxygen-dependent radiosensitivity of the broad bean (*Vicia faba*) root and of mouse Ehrlich ascites tumour cells in the presence of oxygen[1]. The effectiveness of the inert gases follows their partition between water and lipids and is paralleled by their anæsthetic potency. It therefore seemed of interest to test nitrous oxide. Results obtained with nitrous oxide on mouse Ehrlich ascites tumour cells show a marked effect, and, since this gas is effective in the range physiologically tolerated by mammals, it seems worth while reporting the results (Table 1).

Table 1

Experiment	Gas mixture during exposure to X-radiation	Dose in r. to reduce normal anaphases to 31·6 (per cent)	Relative radiosensitivity
1	1 atm. of air	130 ± 10	3·5 ± 0·09
2	0·2 atm. of oxygen + 0·8 atm. of nitrous oxide	500 ± 20	0·91 ± 0·02
3	1 atm. of air + 95 atm. of argon	455 ± 20	1·0 ± 0·04
4	1 atm. of air + 11 atm. of nitrogen	330 ± 15	1·4 ± 0·02
5	1 atm. of air + 2 atm. of xenon	380 ± 15	1·2 ± 0·02

The experimental techniques and the method of evaluation of the results are those described previously[1], except that in Experiment 2 the tumour was fixed 12 hr. after irradiation because the maximum damage occurred then and not after 18 hr., as was the case in the other experiments.

It can be seen from Table 1 (Experiment 1) that the relative radiosensitivity of mouse ascites tumour cells, when exposed to 190-kV. X-radiation in 1 atm. of air, that is, 0·2 atm. of oxygen and 0·8 atm. of nitrogen, was 3·5 ± 0·09. The addition of 0·8 atm. of nitrous oxide to 0·2 atm. of oxygen (Experiment 2) reduced the radiosensitivity to the same extent as 95 atm. of argon (Experiment 3), that is, to the same low level as observed in irradiation under nitrogen alone[1]. Table 1 also shows the results of experiments carried out with the mixtures 1 atm. of air plus 11 atm. of nitrogen (Experiment 4), and 1 atm. of air plus 2 atm. of xenon (Experiment 5). These indicate that nitrous oxide is the most effective of the gases tested in blocking the effect of oxygen on the radiosensitivity of Ehrlich ascites tumour cells.

Acclimatization Status of Temperate-zone Man

When men accustomed to living in a temperate climate are repeatedly or continuously exposed to a natural or artificial hot environment they rapidly develop a greatly increased capacity to withstand heat, and this adaptation is accompanied by profound and readily demonstrable physiological changes. On the other hand, when men are similarly transferred from a temperate to a cold, even arctic, environment
neither do they display the same
tolerance of their new environment n
found possible to demonstrate com
physiological changes. Such marke

Extra-Regional Oocytes in Teleosts

THE occurrence of extra-regional oocytes has been described by several authors in many species of vertebrates[1,2]. Most of these cases related to the genital and the caudal region.

We have observed extra-regional oocytes in the following species: *Phenacogrammus interruptus*, *Chaetodon capistratus*, *Abramites microcephalus*, *Ballistes undulatus*, *Botia modesta*, *Cottus gobio* and *Barbus gelius*. These cases are summarized in Table 1. In general, the cells had the characteristic oocyte structure, namely, granular cytoplasm, oolemma, nucleus with several nucleoli.

The presence of extra-regional oocytes is closely related to the migration of the primordial germ cells. Obviously certain cases may provide important data on the mechanism of the migration.

For the three major theories relating to the migration of the primordial germ cells we refer to the publication of Johnson[2], who observed an amœboid movement in the germ cells of the black bass. Newth[3] stated that in Lacertilians the migration of the primordial germ cells to the gonadal ridges occurs by a definite route. This type of migration has already been known for a long time in lizards and in *Sphenodon*.

Concerning our case of extra-regional oocytes in the brain of *Abramites* it may be difficult for the primordial germ cells to reach the brain (mesencephalon) by Johnson's[2] first two types of migration, for this would involve crossing a great number of obstacles and carrying the cells a long distance. Like the extra-regional oocytes in the brain of *Cirrhina reba*[4], it is therefore very likely that in this case the migration of the germ cells takes place via the vascular route as in *Sphenodon*, the Lacertilians and the birds. These oocytes might have been lost while they traversed the brain region during their migration, after which they could settle in the brain tissue.

The case of the lordotic *Botia* suggests that the presence of the extra-regional oocytes and the degeneration of these cells are a consequence of the embryological disturbances in the caudal region. It is possible that these processes have passed to abnormal places.

It is noteworthy that in the case of *Ballistes* nucleolar extrusion was observed. The tumour in *Barbus* shows that migrated extra-regional oocytes which have migrated can proliferate under certain circumstances.

Table 1. CASES OF EXTRA-REGIONAL OOCYTES IN TELEOSTS

Species	Localization of the oocytes	Extra-regional oocytes	Nuclei of the extra-regional oocytes	Remarks
Phenacogrammus interruptus (length 69 mm.)	Intermuscular connective tissue of the caudal region	Small, medium-sized and large types; infiltration of some large oocytes by strands of connective tissue	Several nucleoli	Externally no peculiarities
Chaetodon capistratus (length 78 mm.)	Intermuscular connective tissue of the caudal region	Medium-sized and large types; some oocytes degenerated	Several nucleoli	Externally no peculiarities
Abramites microcephalus (length 53 mm.)	Brain (mesencephalon)	Small and medium-sized types, sometimes attached to the brain tissue; infiltration of some medium-sized oocytes by strands of nervous tissue	Several nucleoli	Externally no peculiarities
Ballistes undulatus (length 83 mm.)	Intermuscular connective tissue of the caudal region	Small, medium-sized and large types	Several nucleoli, sometimes nucleolar extrusion	Externally no peculiarities
Botia modesta (length 89 mm.)	Intermuscular connective tissue of the caudal region	Small and medium-sized types; some oocytes degenerated but not infiltrated by strands of connective tissue	Several nucleoli	Lordosis
Cottus gobio (length 241 mm.)	Intermuscular connective tissue of the caudal region	Small, medium-sized and large types	Several nucleoli	Externally no peculiarities
Barbus gelivs (length 70 mm.)	Caudal region	No true extra-regional oocytes, probably developed to granulosa cell tumour	—	Irregular, nodular tumour

Conversion of Carbon-14 Dioxide to Starch Glucose during Photosynthesis by Spinach Chloroplasts

THE distribution of carbon-14 in the glucose moiety of sucrose, glucose phosphate and starch formed from carbon-14 dioxide during short-time photosynthesis in *Chlorella* and the leaves of higher plants has been shown to be asymmetric[1]. It was proposed that either glucose was not formed by the condensation of two triose phosphates of similar tracer distribution or that a pool of unlabelled dihydroxyacetone phosphate was present in the cell, causing a dilution of the upper three carbon atoms of the hexose. To test the validity of the latter suggestion, the intact spinach chloroplast free of much cytoplasic material was employed.

In agreement with Allen *et al.*[2], a glucose polymer was the only insoluble product formed under the conditions used. In the 4-min. experiment, the insoluble fraction accounted for 3 per cent of the tracer assimilated while in the 30-min. photosynthesis this fraction increased to approximately 20 per cent.

All the glucoses formed by the spinach chloroplasts during these time periods possess an asymmetric distribution of carbon-14 (Table 1).

Table 1. THE DISTRIBUTION OF CARBON-14 IN STARCH GLUCOSE FORMED BY SPINACH CHLOROPLASTS DURING PHOTOSYNTHESIS IN CARBON-14 DIOXIDE

Exp. No.	Time of exposure	Tracer content of carbon atom number (mμc./mgm. carbon)					
		1	2	3	4	5	6
1	3 min.	0·04	0·01	0·09	0·17	0·05	0·04
2	4 min.	1·02	0·69	1·54	2·42	0·46	0·55
3	30 min.	1·57	1·40	2·14	2·33	1·14	1·10

Chloroplasts were isolated in 0·35 *M* sodium chloride[2]. Unwashed chloroplasts were used in Exps. 1 and 2. Chloroplasts once washed with 0·35 *M* sodium chloride were used in Exp. 3. Warburg vessels (150 ml. capacity) contained the following components (in μmol.) : *tris* (hydroxymethyl) aminomethane buffer, *p*H 7·5, 80 ; sodium ascorbate, *p*H 7·5, 10 ; manganese chloride, 2 ; chloroplasts (5–10 mgm. chlorophyll) suspended in sodium chloride, 1,540. In Exps. 1 and 2, the mixture contained $NaH^{12}CO_3$, 48 and 5 μmol. respectively. In Exp. 3 the carbon-12 dioxide was negligible. The total volume was 4·8 ml.

The side-arm carried 1 μmol. of carbon-14 dioxide as sodium bicarbonate containing in μc. : Exp. 1, 100 ; Exp. 2, 150 ; Exp. 3, 10. After the vessels were flushed with prepurified nitrogen in a bath at 14° C. for 10 min. with the lights on (4,000 foot-candles), the isotopically labelled sodium bicarbonate was tipped in. The light source was Sylvania Birdseye Floodlites (150 watts, 120 volts). The reaction was terminated by heating the cup contents in a boiling water bath for 2 min. After the residue was washed twice in the centrifuge tube with hot water, the starch glucose was derived by hydrolysis with 6 ml. of 1 *N* hydrochloric acid for 45 min. at 100°. The mixture was centrifuged and the residue was washed twice with hot water. The supernatant fluid and washings, brought to approximately *p*H 7·5, were passed through 'Dowex-50' (H^+ form) and 'Amberlite *CG*–45' (OH^- form). The effluent was evaporated to approximately 1 ml. and streaked on to washed sheets (14 cm. × 17 cm.) of Whatman No. 1 paper. The chromatograms were developed with butanol (52 ml.), 95 per cent ethanol (32 ml.) and water (16 ml.). The X-ray film showed only one band with an R_F value corresponding to glucose. This band coincided with the typical hexose colour developed after aniline phthalate spraying. This glucose, together with 400 μmol. of carrier glucose, was degraded with *Leuconostoc mesenteroides*[3]. Activity is expressed in Table 1 as mμc. per mgm. of carbon.

The ratio of carbon atom 3 to carbon atom 1 (C-1, aldehyde carbon) and/or C-2 is less than that of C-4 to C-5 and/or C-6. This type of labelling pattern is similar to that reported by Gibbs and Kandler for glucose formed in intact cells[1]. It would appear that the cause of asymmetry is probably not a relatively large supply of unlabelled dihydroxyacetone phosphate.

The similarity between the tracer pattern of the starch glucose formed by the intact cells and isolated chloroplasts further strengthens the concept that the isolated structure possesses a typical photosynthetic carbon cycle.

This investigation was supported by a grant (*G*-2849) from the National Science Foundation.

Direct Absorption of Dissolved Strontium-90 and Yttrium-90 by Tadpoles of *Rana temporaria*

THE presence of long-lived radioisotopes, for example strontium-90 and cæsium-137, in fall-out material and their detection in soil, vegetation and animal products have been confirmed[1]. The harmful effects of this build-up of radioisotopes can, to some extent, be predicted by reference to earlier experiences with radioactive materials such as radium. There is very little experimental evidence on the direct biological effects of strontium-90 and cæsium-137. A long-term investigation into the life-cycle of the frog has been started and some exploratory results of the turnover of radiostrontium and radioyttrium by the tadpoles of *Rana temporaria* are of interest.

Tadpoles, in batches of 100, from local ponds, estimated to be 5–7 weeks old, were treated with small amounts of strontium-90, about 0·125 μc. in 500 ml. water containing 100 tadpoles, giving $2 \cdot 5 \times 10^5$ disintegrations/min. strontium-90 and yttrium-90. The experiments were conducted in glass tanks ; the exchange of activity by the glass was shown to be small. The water was tested for radioactivity at intervals. The tadpoles were eventually removed from the water, which was filtered through a sintered crucible to collect the insoluble matter, mainly fæces. The fæces were dissolved in hot nitric acid, which was then suitably diluted. A sample of 10 tadpoles was washed, incinerated, extracted with aqua regia and suitably diluted. The tank contents were, therefore, divided into : (1) water ; (2) fæces solution ; (3) tadpole solution.

The activities of all three solutions were measured at further intervals of time using a type *M*6 Geiger–Müller liquid counter and associated *IDL* counting equipment (scaler, probe unit, and extra-high tension unit). The performance of the counting equipment was checked throughout by means of a standard uranium solution. The background was also checked and found to be practically constant at 13 c.p.m. Five

Table 1

Sample	Strontium-90 (c.p.m.)		Yttrium-90 (c.p.m.)		Strontium-90/yttrium-90 at 175 hr.	
	0 hr.	175 hr.	0 hr.	175 hr.	From liquid counts	From solid source absorption plot
Water	34,000 (*A*)	28,000 (*C*)	34,000 (*A*)	9,500 (*B*)	3·0	3·1
Tadpoles	—	6,000 (*E*)	—	19,300 (*D*)	0·31	0·32
Excreta	—	1,500 (*G*)	—	4,000 (*F*)	0·38	—
Totals	34,000	35,500	34,000	32,800	—	—

experiments as above have been carried out to date, and a typical set of results is represented in Fig. 1.

The decay scheme is as follows :

$$^{90}\text{Sr} \xrightarrow[\substack{0\cdot61\text{ MeV.}\\ 28\text{ years}}]{\beta} {}^{90}\text{Y} \xrightarrow[\substack{2\cdot25\text{ MeV.}\\ 64\text{ hr.}}]{\beta} {}^{90}\text{Zr}$$

It is apparent that the liquid counter is measuring mainly the 2·25 MeV. β-emission of yttrium-90 and very little of the strontium-90 0·61 MeV. β-emission. The glass wall thickness is about 35 mgm./cm.[2] but the effective absolute thickness may be several times this value[2]. The initial drop in curve *AB* is due mainly to absorption of yttrium with some strontium by the tadpoles. The levelling out of *AB* is probably due to the absorption of yttrium as soon as it is formed from the strontium remaining in the solution. After separation of the tadpoles and fæces, the count on the water rises along curve *BC*. This indicates the growth of yttrium in the water from the strontium remaining, until a fresh secular equilibrium is reached at *C*. This value at *C* represents the yttrium now in equilibrium with the strontium not removed by the tadpoles. The counts on the tadpole solution *DE* and the fæces solution *FG* decrease with passage of time to constant levels at *E* and *G*.

Points *C*, *E* and *G*, therefore, represent the amounts of strontium-90 in the water, tadpoles and the fæces respectively at the time of separation, that is, 175 hr. Points *D*, *B* and *F* represent mainly the yttrium-90 content of the three solutions at separation.

Thus, the tadpoles have a strontium-90/yttrium-90 ratio at separation of 6,000/19,000 or 1/3·1. An absorption plot was carried out on an aliquot of the tadpole solution evaporated to dryness on a planchette and almost the same strontium/yttrium ratio was obtained. All the results are summarized in Table 1.

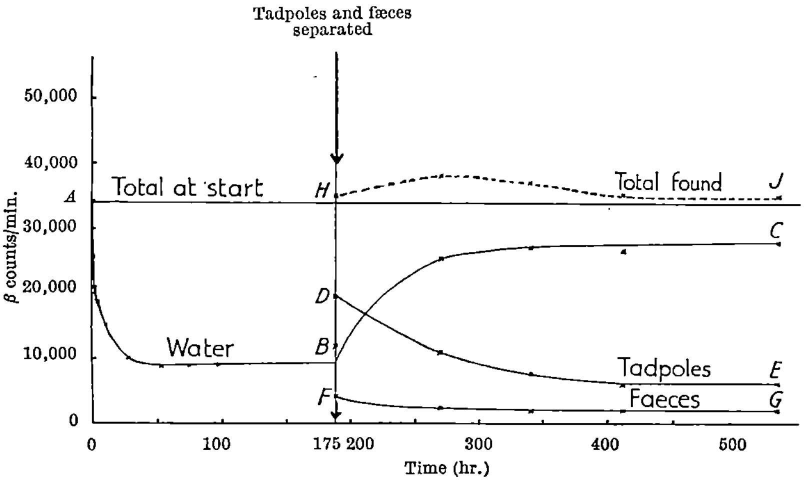

Fig. 1

The 100 tadpoles absorbed in about one week approximately 18 per cent (~0·02 μc.) of the strontium-90 and about 72 per cent (~0·09 μc.) of the yttrium-90.

Attempts were made to wash the strontium-90 from the tadpoles with water, but, even after four weeks, the tadpoles still had a strontium-90 content not appreciably lower than indicated by point *E* (Fig. 1). Ethylenediamine tetraacetic acid (0·01 per cent) solution increased the rate of decontamination. Preliminary investigations indicate that calcium bicarbonate added to the tank results in a lower uptake of strontium-90 by the tadpoles, although the curves obtained are similar to those for soft water. Histological changes and the effect on metamorphosis are being investigated.

Phagocytosis and the Antigenic Structure of Bacteria

Phagocytosis is one of the mechanisms underlying immunity against infection. In spite of numerous investigations, our knowledge concerning this mechanism is still inadequate. No systematic studies have been conducted on the significance of the antigenic structure of bacteria in the process of phagocytosis, and the data on substances contained in the blood serum promoting phagocytosis and referred to as opsonins or tropins are also inadequate.

The present experiments aimed at elucidating the importance of antigenic structure of bacteria in the phagocytosis process in the case of Gram-negative intestinal bacilli with known antigenic structures.

Horse sera from healthy, non-immunized horses were used in all experiments. These sera were inactivated on the day of experiment for 30 min. at a temperature of 56° C. in order to exclude the participation of the complement, and were used in an undiluted state.

Leucocytes from horse blood were obtained by centrifugation of mechanically defibrinated blood ; they were washed five or six times by centrifuging

Table 1. PHAGOCYTOSIS OF BACTERIA WITH *K* ANTIGENS

with physiological saline at the speed of 2,000 r.p.m. The leucocytes were used for experiments 3–4 hr. after the blood had been taken.

The strains used for experiments were : *Salmonella, Shigella, Alkalescens-Dispar, Escherichia* and *Brucella*. The bacterial suspensions were washed with physiological saline to remove any soluble antigens which might affect the results of the phagocytic reaction. The suspensions to be examined were checked for the presence or lack of the *K, O* and *R* antigens.

The phagocytic reaction was performed by the tube method ; one volume of washed leucocytes was mixed with one volume of inactivated undiluted serum and with one volume of the suspension of the bacterial strain under examination. After rough mixing, the tubes were placed in a water-bath at 37° C. for 20 min. (In control tests physiological saline was used instead of horse serum ; the time of phagocytosis was prolonged to 60 min.) After drying in air, the preparations were fixed by passing them three times over a flame and then for 20 min. in methyl alcohol. The preparations were then stained with undiluted Manson dye by immersion for 3–5 sec. ; afterwards they were thoroughly washed and dried in air.

Counts were made using an oil-immersion objective. The phagocytic index was calculated by dividing the number of bacteria digested by 100 leucocytes by 100. In view of the difficulty of counting bacteria when their number exceeded 40, the actual index above 40 was assumed, not calculated.

To minimize the possibility of side-effects, the suspensions were prepared in a separate room, and the persons reading the results (invariably the same) did not know what bacteria had been used in any given investigation.

The tabulated results present the mean values from six experiments. It is to be stressed that no pronounced differences could be found between particular sera.

The results summarized in Tables 1–3 point to a close relation between the antigenic structure of bacteria and the degree of phagocytosis in the presence of normal, inactivated and undiluted horse serum.

Pronounced differences were found in the phagocytosis of smooth (*S*) and rough (*R*) forms as well as in the phagocytosis of *S*-forms depending on their antigenic structure. These differences were to be seen both with the use of naturally dissociated forms and with suspensions in which some antigens had been destroyed by heating at temperatures of 60°–120° C.

It is of interest that there is complete agreement between the results obtained in the phagocytic reaction and those by serological methods, used as a matter of routine in the experiments on the antigenic structure (agglutination, absorption tests).

The results contained in Table 1 point to the great importance of the surface antigens (*Vi, M, L, B, A*) for the phagocytosis of bacteria which possess them. *K* antigens exert a pronounced inhibitory effect on phagocytosis. A clear-cut relation could be established between heat susceptibility and the extent of phagocytosis.

Table 2. PHAGOCYTOSIS OF BACTERIA WITHOUT *K* ANTIGENS

Antigen	Strain	Heat susceptibility of antigen	Kind of suspension				Control
			f	60° C.	100° C.	120° C.	
—	*S. flexneri X*	—	4·61	>40	>40	>40	0
—	*S. flexneri Y*	—	10·20	>40	>40	>40	0
I	*S. flexneri* 1*b*	—	0·78	1·83	>40	>40	0
III	*S. flexneri* 3	—	0·46	4·38	>40	>40	0
alpha	*DRL* 358/55	100° C.	0	1·90	>40	>40	0
beta	*E. coli* C_3	100° C.	1·92	4·32	>40	>40	0
1*F*	*S. flexneri* 6	120° C.	0	2·75	37·50	>40	0

The results in Table 2 suggest the possibility of differentiating the bacteria in which no *K* antigen could be found (*O* forms). Here, too, differences in the degree of phagocytosis were observed depending on the heat susceptibility and the character of antigen (the presence of thermolabile α-, β-, 1*F* antigens ; the presence or lack of type antigens).

The results in Table 3 suggest the possibility of differentiation between the smooth (*S*) and rough (*R*) form and the detection of the transitional *SR* forms. It was found that *R* forms are also phagocytized in the absence of serum ; this fact distinguishes them from *S* forms, which undergo no phagocytosis in these conditions.

The results presented indicate the great importance of the structure of the bacterial cell in the phagocytic process. They also suggest new possibilities of studies

Table 3. PHAGOCYTOSIS OF SMOOTH (*S*), ROUGH (*R*) AND TRANSITIONAL *SR* FORMS

on the antigenic structure of bacteria by the application of the phagocytic reaction.

The experiments shed some light on the efficiency of the mechanism of phagocytosis depending on the character of infecting bacteria. They also suggest the importance of an as yet unknown factor, contained in the normal horse serum, for the phagocytic process of smooth bacterial forms.

The phagocytic test proved to be more sensitive than serological reactions in the detection of differences in the antigenic structure of bacteria (for example, in the detection of transitional forms).

Longevity of *Proteus* Group of Amœbæ

Explanation (1) of the findings described by Muggleton and Danielli[1] appears to fit in best with the facts enumerated below.

The normal life-cycle of the *Proteus* group of amoebae consists of four well marked stages: (*a*) spore, (*b*) developing juvenile, (*c*) adolescent, (*d*) mature to senile. It is the adolescent and young adult that can be made to reproduce indefinitely by binary fission. As soon, however, as a rigid control of their environment is relaxed, they proceed with their life-cycle. Chromidia from the nucleus escape into the cytoplasm and develop into spores. When the individual becomes filled with spores it dies. If, however, these spore-filled individuals are placed in a Petri dish and killed by a change in *p*H, the hatching of the spores, and their subsequent development, given a suitable pabulum, can be observed. It has been shown why this development is slow[2]. I am at present engaged in trying to accelerate this growth, and am glad to record here the gift of supplies of bacteria and lettuce-water sent to me by Dr. Muriel Robertson of the Lister Institute.

Growth and Maturity of the Barnacles *Lepas hillii* and *Lepas anatifera*

Information on the rate of growth of all species of *Lepas* is scanty. Stanley Kemp, in a letter to J. F. Anton[1], quotes three sources, the first of which, referring to an unspecified *Lepas*, gives an increase in capitulum length of about 1 mm. a day; the second and third, referring to *L. anserifera*, give increases of 8 mm. in 8 days, 21 mm. in 40 days and 25 mm. in 107 days. In all cases these are minimum rates since they refer to ships and to a buoy known to be free of barnacles at one date and supporting barnacles of quoted size at another, the moment of settling being unknown.

During the voyage of the yacht *Petula* from Dakar to Barbados in the winter of 1953–54 [2], colonies of barnacles settled on the ship's side above her anti-fouling paint and flourished there throughout the passage. While the ship lay in Dakar harbour preparing for sea, the stores which were loaded into her so increased her draught that some of her white topside paint was submerged, and here many fouling organisms were able to gain a hold. So long as the ship was at anchor only the sessile barnacle *Balanus amphitrite* Darw. was present, but at sea this species largely died off and was replaced by the pedunculate barnacles *Lepas hillii* Leach, *Lepas anatifera* L. and *Conchoderma virgatum* (Spengler). *Conchoderma virgatum* was present in large numbers and early attained a capitulum length of 9 mm. but beyond this length it did not grow, being heavily preyed upon by the trigger fish *Canthidermis maculatus* and *C. sobaco*.

In position 15° N., 31° W., after the ship had been at sea for 30 days, a sample of twenty of the largest *Lepas* growing on the topside was taken and preserved. A further sample of sixty of the largest specimens from an adjacent position was taken after 60 days, in position 15° N., 46° W.

Measurement of the preserved material yielded results summarized in Table 1. The measurements, to the nearest 0·5 mm., were made from the umbo (basioccludent angle) of the scutum to the upper (occludent) tip of the tergum. This dimension may be approximately equated with the capitulum length generally quoted in the literature, being very slightly greater; it is to be preferred to the capitulum length as giving a firmer standard of size.

Table 1. Length Distribution of *Lepas* taken 30 and 60 Days Out

Length (mm.)		11–13·5	14–16·5	17–19·5	20–23
30 days	Total *L. hillii*	3	4	2	0
	Gravid *L. hillii*	0	1	0	0
	Total *L. anatifera*	5	6	0	0
	Gravid *L. anatifera*	0	2	0	0
60 days	Total *L. hillii*	6	10	20	21
	Gravid *L. hillii*	0	2	16	11
	Total *L. anatifera*	0	0	1	2
	Gravid *L. anatifera*	0	0	0	1

The age of the barnacles in the samples is again not known with certainty since settlement on the ship's side was not observed. Colonies containing both species of *Lepas* were established 10 days out, with capitula of perhaps 5 mm., and from the first day out the ship passed among much flotsam bearing mature *L. anatifera* from which infection by this species could have occurred. No *L. hillii* were found on collected flotsam, yet it is certain that both species were well established on the tenth day and it is not unreasonable to suppose that settlement of both began very near to the start of the voyage.

All specimens were opened and searched for embryos. From Table 1 the following may be noted.

(*a*) Among the 30-day group only one specimen of *L. anatifera* among eleven and one of *L. hillii* among nine bore embryos in the ovigerous lamellæ. It therefore seems probable that both species require more than 30 days on average from settlement to maturity.

(*b*) Of the 60-day group of *L. antifera* one out of three bore embryos. Twenty-nine out of fifty-seven *L. hillii* bore embryos, all except two of the gravid examples being longer than 16·5 mm. So large a proportion of the barnacles between 17 and 19·5 cm.

contained embryos that it is probable that this span represents first maturity. Since *L. hilli* achieved, in general, a length of 13–17 mm. in 30 days, 17–19·5 mm. at maturity and 17–21 mm. in 60 days it might be crudely assumed, given a constant increase in length during the second month, that maturity was achieved, on average, in the last two weeks of the second month. Comparing lengths at 30 and 60 days, however, it is seen that the average daily increase of about 0·5 mm. in the first month is not maintained in the second. This check in growth was no doubt due to the attainment of maturity at 17–19·5 mm. It would therefore seem more probable that the growth-rate of 0·5 mm. a day observed in the first month continued to maturity, which on these terms occurred in general on the thirtieth to forty-third day. Thereafter, a growth-rate near 0·03 mm. a day is indicated.

Throughout the voyage the sea temperature was high, ranging from 24·2° to 26·1° C. The conclusions advanced above concerning both growth-rate and the length of the juvenile phase must consequently be applied with caution to animals taken in cooler waters.

Occurrence of Forms of *Fucus distichus* L. emend. Powell on North Rona and Sula Sgeir

Fucus distichus L. emend. Powell is an extremely polymorphic alga, widely distributed principally on arctic and sub-arctic coasts, and I have recently proposed[1] the recognition of four principal subspecies of this plant. Two of the subspecies—subsp. *edentatus* (De la Pyl.) Powell (a large plant of sheltered shores), and subsp. *anceps* (Harv. et Ward ex Carruthers) Powell (a small plant of exposed shores)—have southern limits in northern and western parts of Scotland and Ireland[2], and are the rarest fucoids in Britain.

As a member of the Glasgow University North Rona Expedition (June 23–July 23, 1958)[3], I have recently been able to investigate the botany and littoral ecology of the small, remote Scottish islands of North Rona and Sula Sgeir which lie about 45 miles north-west of Cape Wrath. Subsp. *anceps* was found on both islands, in small quantity but at several sites in each case, at its usual high level on shores exposed to severe swell and wave action. Subsp. *edentatus* was found on North Rona only, in the moderately sheltered inner parts of two narrow geos facing north and north-east respectively, in the north-eastern part of the peninsula of Fianuis. In the north-facing geo, only a few young (non-fertile) plants were found on large mid-littoral boulders; but in the north-east-facing geo, subsp. *edentatus* formed a distinct belt (of varying depth) in the upper half of the mid-littoral zone, along about 25 m. of shore each side of the geo, and both young (non-fertile) and older (fully fertile) plants were present. The largest plant was 42 cm. in length. Several plants of both sub-species have been examined in detail; caecostomata[1] were present in all, and the conceptacles were hermaphrodite. The only other fucoid found was *F. spiralis* L. (mostly f. *nana*)—very scarce on North Rona only.

The present findings confirm previous observations[2] that subsp. *anceps* can survive more severe exposure conditions than any other fucoid in northern Britain; and these records from such small and isolated islands strengthen my belief[2] that subsp. *anceps* is a relict plant in Britain, a survivor from a period when the climate here was colder.

Subsp. *edentatus* has been reported previously from only three localities in Britain (in the harbours of Lerwick and Scalloway in the Shetland Isles, and in the North Haven on Fair Isle)[2]; the North Rona records therefore establish a new southern limit for the plant on the British side of the North Sea. I have suggested elsewhere[2] that subsp. *edentatus* may have been introduced to the Shetland and Fair Isle localities within recent centuries, perhaps by fishing boats; but it seems scarcely likely that it could have been introduced to North Rona in this way, even though we saw as many as four Norwegian fishing boats at a time anchored close inshore there during periods of rough weather. The possibility of introduction by floating plants cannot be ruled out, of course, but this seems not very likely in view of the prevailing winds and currents. There remains the possibility that subsp. *edentatus* has been present on North Rona, and perhaps at the other three Scottish localities, a very long time—a relict plant, as subsp. *anceps* appears to be; I now much incline to this view.

A detailed report on the littoral flora and fauna of North Rona and Sula Sgeir is being written in collaboration with my colleague Mr. T. B. Bagenal, and will be published elsewhere.

Selection of Cell Lines in Tissue Culture by the Use of Cytotoxic Antisera

THE cytotoxic action of antisera against nucleoproteins isolated from HeLa, H.Ep. No. 1 and MCN cells has been previously reported from this laboratory[1,2]. Of particular significance was the observation that only cell lines exhibiting epithelial-like morphology (Ep. L) were destroyed by the HeLa and H.Ep. No. 1 antisera, while cells with fibroblast-like morphology (Fb. L) were affected only by the MCN antisera. Consistently, cultures of susceptible cells were completely destroyed by a 1 : 50 dilution of cytotoxic antisera in the presence of guinea pig complement. During the course of these investigations, an established strain of human amnion cells was encountered the behaviour of which toward HeLa and MCN antisera was different from that of cell lines previously examined. A fraction of the cell population was resistant to the MCN antiserum and a fraction was resistant to the HeLa antiserum, even when the antisera were employed at 1 : 4 dilution. It is the purpose of this communication to report the selection of two cell lines from the human amnion strain. These two sublines can be distinguished on the basis of their morphological characteristics, their capacity to support virus multiplication, and their sensitivity to the HeLa and MCN antisera.

The human amnion strain was obtained through the kindness of Dr. L. Hayflick from the Tissue Culture Laboratory of the University of Texas, Galveston, Texas. The establishment and development of this cell strain have been described recently by Fernandes[3]. From its initial isolation, this strain has exhibited epithelial-like characteristics. It has not undergone any of the changes often associated with the development of an established cell line from a primary culture[4]. The cell supported with evident cytopathogenic changes the growth of a number of viruses, including types I, II and III poliomyelitis[3].

The human amnion strain was received in this laboratory on January 21, 1958. It was observed that the cells grew vigorously, although their general growth pattern was not typical of that associated with epithelial-like elements. The cells were mainly of the fusiform type. During initial experiments with poliomyelitis virus, no obvious cytopathology could be ascertained. The cells were tested for their susceptibility to the HeLa and MCN nucleoprotein antisera by the method described[1,2]. Neither antiserum, even at low dilutions, was capable of destroying all the cells. The HeLa antiserum destroyed a maximum of 10–15 per cent of the cell population while the MCN antiserum destroyed at most 85–90 per cent of the cells. Identical results were obtained with undiluted antisera and with antisera diluted 1 : 10, indicating that over this range the percentage of cells destroyed by the antisera was not a function of the concentration of cytotoxic antibodies. Attempts were then made to isolate the two types of cells by means of selective destruction by the two antisera. The procedure followed is described below.

Cells were grown on glass (prescription bottles, 8 oz.) in a medium consisting of 10 per cent horse serum in Eagle's basal medium[5]. They were scraped from the glass wall and suspended in growth medium to give a concentration of 10^6 cells/ml. 2 or 3 ml. aliquots of this suspension were incubated with HeLa or MCN antisera (final dilution 1 : 4) in the presence of guinea pig complement. After 2 hr. the percentage of surviving cells was recorded, the cell suspensions were centrifuged, and the sedimented cells were planted in separate bottles in 90 per cent Eagle's medium and 10 per cent horse serum.

In a successful experiment, growth was observed after treatment with the antisera. Cells that had survived the MCN antiserum treatment grew as separate colonies, each cell having polyhedral contours and large areas of contact with its neighbours. These characteristics were recognizable as epithelial (Ep. L). In contrast, those cells that had survived HeLa antiserum treatment were mostly fusiform with filamentous processes and had no tendency to form separate colonies. This morphology and growth pattern are associated with fibroblasts (Fb. L). Cells of the first type (Ep. L) were completely destroyed by the HeLa antiserum while MCN antiserum completely destroyed the second (Fb. L) type. The two sublines were then transferred and separately maintained. The isolated human amnion sublines were tested for sensitivity to the three types of poliomyelitis virus. The virus pools employed were cultures of monkey kidney cells infected with the virus agents. The results of titrating these three pools in tubes of the amnion Ep. L and Fb. L lines, as well as the initial titre in the monkey kidney cultures are shown in Table 1. All three types of polio produced cytopathogenic changes in the Ep. L line through 10^{-5}–10^{-6} dilutions of virus, while no cytopathology was observed in the Fb. L line even at the highest virus concentrations. Production of type II polio virus by the two sublines was studied by back titration of infected culture fluids on monkey kidney cells. Ep. L cells were exposed to a 10^{-5} dilution of type II virus ; the medium was harvested and titrated on monkey kidney cells through five serial ten-fold dilutions. A five-log increase in virus concentration was demonstrated in the Ep. L cells. By contrast, when culture fluids from the Fb. L cells were titrated in monkey kidney cultures, no increase in virus concentration could be demonstrated. Several passages of type II polio in the Fb. L cells yielded no virus as could be determined by back titration in monkey kidney.

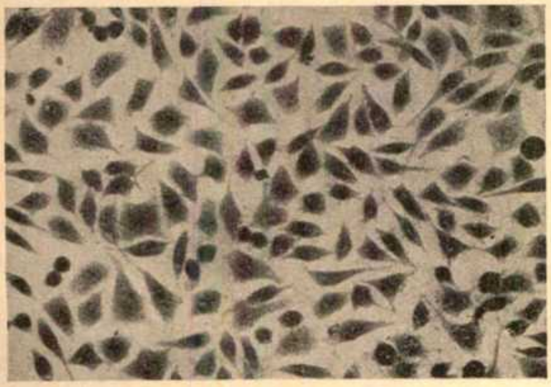

Fig. 1. Human amnion, Fb. L subline. Hæmatoxylin and eosin. (× 160)

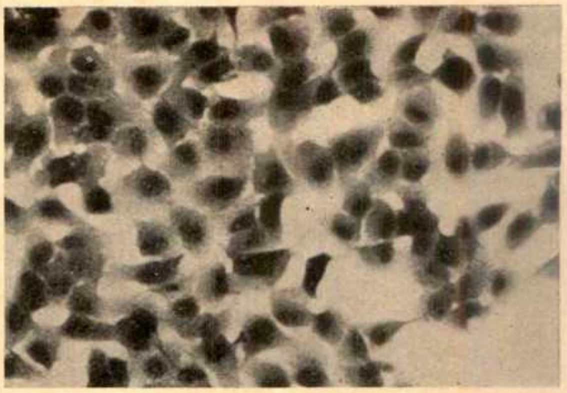

Fig. 2. Human amnion, Ep. L subline. Hæmatoxylin and eosin. (× 160)

During four months of observation, the Fb. L line has remained unchanged, while in the Ep. L line there has been a constant increase in the number of cells sensitive to the MCN antiserum. This tendency has been controlled by periodic treatment of the cells with MCN nucleoprotein antiserum until a stable epithelial line was obtained. In some bottles which have not received this treatment, the MCN antiserum-sensitive cells have increased after four transfers to the level observed in the original culture (85–90 per

Table 1. TITRATION OF TYPES I, II AND III POLIOMYELITIS VIRUS IN MONKEY KIDNEY, AMNION EP. L AND AMNION FB. L CELLS

* Expressed as logarithms to the base 10.
† No cytopathology seen at any virus concentration.

cent). This phenomenon probably represents the more rapid proliferation of some fibroblast elements left among the epithelial cells, a possibility which is being studied by cloning techniques. In addition, the number and morphology of the chromosomes, the growth characteristics, and certain biochemical properties of the two cell lines are under investigation.

It is of particular interest that the cellular morphology is significant with respect to virus susceptibility[6,7] and that a cell type with certain specific characteristics can be rapidly selected by the application of antisera to a mixed cell culture.

This work was supported by grants from the American Cancer Society (*E*-88 and *E*-89) and from the Public Health Service (*CY*-3411).

Antigenicity and Survival of Cartilage Homografts

DURING the course of investigation of the reasons underlying the ability of cartilage grafts to survive in foreign hosts for long periods, the effects of cartilage homografts and heterografts on the regional lymph node were studied in order to determine whether such grafts were antigenic[1]. The results of this test indicated that both types of graft do evoke an active immune response in the host animal, and it was discovered, further, that heterografts do so even after having been boiled for periods of up to 10 min.[2]. This test does not, however, indicate whether the host animal becomes fully immunized by the foreign cartilage, and in order to determine whether this is so, rabbits bearing cartilage homografts have been challenged with skin homografts from the cartilage donor.

Thirty-six rabbits were used in the investigation. Eighteen control rabbits received a fitted skin homograft of 1½ in. × ½ in. Eighteen experimental animals were given 0·2 gm. of diced homologous cartilage on each of two occasions four days apart, followed by a fitted 1½ in. × ½ in. skin homograft from the cartilage donor on the fourteenth day after the second cartilage implant. A skin homograft of 0·36–0·44 gm. weight will fully immunize an adult rabbit within 14 days[3]. All 36 skin homografts were removed on the sixth day after grafting, and 7μ paraffin sections were stained by hæmatoxylin and eosin. The graft condition was assessed histologically, using the following classification: (*A*) survival, with proliferation, of the entire graft epithelium; (*B*) breakdown of proliferated or still proliferating epithelium in progress; (*C*) breakdown of non-proliferated graft epithelium in progress or complete. 'Immune' type of breakdown.

The results are presented in Table 1. They indicate that, in the majority of cases, implantation of 0·2 gm. of homologous cartilage from the same donor on two occasions is insufficient to elicit a state of transplantation immunity in the host. Only five (28 per cent) of 18 rabbits so grafted appear to have become fully immune.

Table 1

Graft condition	Control animals	Experimental animals
A	8	4
B	10	9
C	0	5

This finding raises the question of whether cartilage homografts survive because of their mild degree of antigenicity. This does not appear to be the case, since further experiments I have carried out show that cartilage homografts can survive in animals fully immunized by skin homografts from the same donor. These findings will be published in greater detail elsewhere. The ability of cartilage homografts to survive may therefore well be attributable to the peculiar physico-chemical character of the matrix, as was first postulated by Bacsich and Wyburn[4]. The matrix would appear to behave after the fashion of the semipermeable diffusion chamber devised by Algire, Weaver and Prehn[5], which allows foreign cells to survive in an immune host.

A Technique for the Investigation of the Competitive Saprophytic Ability of Soil Fungi by the Use of Easily Decomposed Substrates

THE method commonly used to determine the competitive saprophytic ability of soil fungi consists of exposing suitable substrates to colonization by the fungus in non-sterile soil. A serious disadvantage of this method is that only relatively resistant substrates, for example, wheat straw, can be used effectively because of the manipulation to which the substrate has to be subjected after incubation. Less-resistant substrates such as portions of non-woody roots, rhizomes and cylinders or disks of storage parenchyma of carrots or potatoes, etc., are so softened by the action of soft-rotting organisms in the soil that it becomes difficult to cleanse them adequately of adhering soil, and hence to state with confidence that fungi isolated from them have actually colonized the substrate in competition with the general soil microflora. It is very important to test the suitability of any potential substrate, for, as Garrett[1] has pointed out in the case of root-infecting fungi, one is usually trying to demonstrate a negative character, that is, inability to compete as a soil saprophyte, and to obtain the strongest circumstantial evidence the killed host must be used as the substrate. A substrate such as wheat straw can probably only yield evidence relevant to fungi pathogenic to wheat or at most to cereals;

hence the need to be able to employ any substrate that suggests itself. Since the chief obstacle to the use of soft tissues as substrates is the difficulty of removing the unwanted soil, the present method has been designed to prevent all unnecessary contact with the soil.

The rhizome of *Convolvulus sepium* was the substrate used in the development of this technique. Lengths of rhizome were washed free from soil, blotted dry, wiped with a pad of cotton-wool soaked in 95 per cent alcohol and washed again in tap water. When dry the pieces of rhizome were placed inside 1¼ in. lengths of sterilized glass tube of suitable diameter and trimmed until approximately ⅛ in. of tissue protruded from each end of the tube. A number of tubed substrates were exposed to propylene oxide vapour in a sealed container for 44 hr. Rhizome thus treated yielded no fungi when plated on potato dextrose agar. The sterile tubed substrate was then exposed to colonization by fungi in various soil/inoculum mixtures maintained at a pre-determined moisture content. At the end of the incubation period batches of ten tubed substrates, which had been placed horizontally in the soil, were recovered and treated as follows: The protruding ends were trimmed off and the tubes placed in a 250-ml. beaker. They were washed in a strong jet of water, using about 500 ml. of water in all. The rhizome segments were then removed from the tubes, washed in two changes of tap water, shaken in 50 ml. of 0·1 per cent mercuric chloride in 10 per cent alcohol for 1 min. and finally washed in three 100-ml. portions of sterile streptomycin sulphate solution (51·8 I.U./ml.). The washed substrates were then plated on potato dextrose agar and incubated at 25° C. for 10 days.

Table 1 illustrates the use that is being made of this technique in a study of the ecology of some members of the genus *Cylindrocarpon* Wollenweber. The results were obtained by examining the incubated substrates and the surrounding medium for the characteristic macroconidia of these fungi. An arbitrary method of scoring was used, 10 units being given to each rhizome segment which yielded macroconidia. Some species of *Cylindrocarpon* tend to produce mostly microconidia which are less characteristic of the genus than the macroconidia. Segments bearing only microconidia were therefore disregarded, even though it was extremely likely that the test fungus had colonized the segment. *Fusarium culmorum* was included in the tests for comparative purposes since several workers have shown that this organism possesses a high degree of competitive saprophytic ability.

These results indicate that this technique is sufficiently sensitive to distinguish between the competitive saprophytic ability of members of the same genus. The technique can be adapted in various ways. For example, by cutting the substrate into 2 mm. sections and plating these in known sequence on agar, information can be obtained not only about the ability of a fungus to colonize the substrate in competition with the general soil micro-flora but also about its rate of spread along the substrate.

Table 1. PERCENTAGE COLONIZATION OF RHIZOME SEGMENTS OF *Convolvulus sepium* BY *Cylindrocarpon* spp. AND *Fusarium culmorum* IN A RANGE OF INOCULUM/SOIL MIXTURES

Percentage inoculum/soil	0	2	10	50	90	98	100
F. culmorum	100	100	100	100	100	100	100

A Direct Method for Determination of Forward-Mutation Rates in *Neurospora crassa*

THE main difficulty in estimating forward-mutation (from wild type to mutant) rates at specific loci in micro-organisms is the determination of the total number of specific mutations in a given population of cells after mutagenic treatment. In general, mutation rates are so low that the number of specific mutants cannot be readily determined by direct methods. An attempt has been made to determine forward-mutation rates at specific loci[1] by indirect methods, using the 'filtration-concentration' technique, which permits only partial recovery of the induced mutants. Later, an effort was made to determine what proportion of the total mutants induced at each of these loci is recovered with such techniques, by reconstruction experiments in which various mixtures of wild-type and mutant conidia were used. To circumvent the various assumptions that must be made to obtain estimates of the forward-mutation rates from the data obtained by such indirect methods, we developed an experimental technique that permits the estimation of the forward-mutation rates of specific loci by a direct method.

The colonial microconidiating albino (*al*-2) strain, 76–*OR*2–7*A*, gives white spherical colonies with very restricted growth-rates either on solid media in Petri plates or in viscous media in liquid culture. Success of the new method depends on morphological distinction between certain mutants and wild type in such a genetic background. In *ad*-3 mutants, a purple pigment is accumulated in the mycelium that readily distinguishes such mutants from wild type. Moreover, production of this pigment can be enhanced by use of growth-rate-limiting levels of adenine and by incubation at 37° C. Thus intermediate alleles with only partial requirements for adenine can also be recovered. After mutagenic treatment of conidial suspensions of strain 76–*OR*2–7*A*, aliquots were inoculated into 20-l. bottles filled with 12–15 l. of minimal medium supplemented with 1 μgm. of adenine sulphate per ml. and made viscous by the addition of 0·15 per cent agar. In this medium, individual conidia are kept well separated and, instead of clumping together, develop into distinct spherical colonies. The medium is stirred by slow aeration through a 6-mm. glass tubing constricted at the tip. All bottles were incubated at 37° C. When individual colonies had developed into spheres 2–3 mm. in diameter, the contents of each bottle were poured into white enamelled developing trays (40 cm. × 60 cm.) to form thin layers. The purple adenine mutants were recovered on the basis of the characteristic purple

Table 1. The Frequency of X-Ray Induced Forward Mutations at the *ad*-3*A* and *ad*-3*B* Loci

Dose (kr.)	Survival		Total purple mutants	*ad*-3*A* mutants			*ad*-3*B* mutants		
	No. of conidia analysed $\times 10^6$	Percentage of initial		No. found	Mutants per 10^6 viable conidia		No. found	Mutants per 10^6 viable conidia	
					Initial	Surviving		Initial	Surviving
None	7·60	100·0	0	0	—	—	0	—	—
4·5	6·64	87·5	16	3	0·39	0·45	13	1·7	2·0
18	5·12	67·4	26	5	0·66	0·98	21	2·8	4·1
36	2·28	30·0	76	13	1·71	5·70	63	8·3	27·6
72	0·4	5·3	73	14	1·84	35·0	59	7·8	147·5

colour of the mature colonies. The total number of colonies in each bottle was estimated by dilution and plating of an aliquot from the control and treated series.

Since phenotypically indistinguishable *ad*-3 mutants originate by mutation at two separate but closely linked loci[2] (individual mutants can be identified as being *ad*-3*A* or *ad*-3*B* by heterokaryon tests), the mutation rates of two loci can be compared under the same conditions. The system also permits an investigation for specificity of mutagens since a comparison can be made of the proportion of the two types of *ad*-3 mutants after treatment of wild type with various types of mutagenic agents.

In an experiment for determining the rates of forward-mutation after X-ray treatment, aliquots of a conidial suspension were left untreated or irradiated with doses of 4·5, 18, 36 or 72 kr. Survival rates and the total number of purple mutants obtained with each treatment of the five aliquots of conidia are given in Table 1. No mutants were recovered from untreated conidia, and a total of 191 mutants were recovered from the four X-ray treatments. Genotypes of individual purple mutants were determined in subsequent heterokaryon experiments in which *ad*-3*A* and *ad*-3*B* tester strains were used. Since more purple mutants were recovered in this one experiment than in all other forward-mutation experiments combined[3], it was of interest to determine whether all such mutants were restricted to only the two known types: *ad*-3*A* or *ad*-3*B*. Since all the 191 mutants gave a positive heterokaryon test with one tester strain and a negative test with the other, all mutants were either *ad*-3*A* or *ad*-3*B*. No double *ad*-3*A* *ad*-3*B* mutants were recovered and no evidence was obtained for the presence of other loci giving phenotypically purple mutants in either the *ad*-3 region or elsewhere in the chromosome complement. Of the 191 purple mutants, 35 were *ad*-3*A* mutants and 156 *ad*-3*B* mutants.

A comparison of the total numbers of *ad*-3*A* mutants and *ad*-3*B* mutants gives a ratio of 1 : 4·5. This difference in the recovery of the two types of mutants was not unexpected since the combined data from numerous forward-mutation experiments in which the 'filtration-concentration' technique was used indicated an excess of *ad*-3*B* mutants. The present experiment provides direct evidence for a greater sensitivity to mutation as a result of X-irradiation of the *ad*-3*B* locus than the *ad*-3*A* locus. In Table 1, it can be seen that the induced rate of mutation of the *ad*-3*B* locus is about 4–5 times as high as the *ad*-3*A* locus at each dose level tested.

Although a microconidial strain was used in this experiment, the shape of the survival curve was not that expected[4] from a strain with only uninucleate conidia. The data suggest that a portion of the conidia was not uninucleate; thus the mutation rates for each locus were calculated on the basis of mutations per conidium, rather than in terms of mutations per nucleus or chromosome. By extension of the experimental points, maximum forward-mutation rates with this strain expected at a dose of 55 kr. are 9·7 and 2·1 per 10^6 viable conidia treated for the *ad*-3*B* and *ad*-3*A* locus, respectively.

Some Observations on the Life-Cycle of *Atoxoplasma*, with Particular Reference to the Parasite's Schizogony and its Transmission by the Mite *Dermanyssus gallinae*

Since it was first shown that *Toxoplasma* infections may occur naturally in some birds (notably pigeons and chickens) there has been considerable speculation on the possible role of wild birds as host reservoirs for human *Toxoplasma* infections.

Although there have been many reports of *Toxoplasma* in a wide variety of wild birds, a large number of these observations are due to confusion of this parasite with hæmogregarines, schizonts of hæmogregarines, coccidial merozoites and exoerythrocytic stages of *Plasmodium*. One parasite even more frequently mistaken for *Toxoplasma* is *Atoxoplasma*[1]. This confusion is not surprising, when diagnosis is restricted to observations on the individual organism, for the two parasites are morphologically very similar. Their superficial resemblance to one another, failure to demonstrate any other stages in their life-cycles and the common habitat of both parasites in the cells of the lymphoid–macrophage system of the host have drawn many authors to the conclusion that *Atoxoplasma* and *Toxoplasma* are at least very closely related.

The following preliminary report is a summary of some recent studies of *Atoxoplasma* and clearly indicates that this parasite is much less closely related to *Toxoplasma* than was previously supposed.

The opportunity to study *Atoxoplasma* arose when I found 100 per cent of adult house sparrows (*Passer domesticus domesticus*) examined to be infected: these birds were trapped in the St. Albans area of Hertfordshire.

Later in the year it was established that young sparrows became infected, at an early age, while still in the nests: obviously, then, the mode of transmission was an extremely efficient one.

Large numbers of fledgling sparrows were trapped: all were infected, some very heavily. Many of these birds died in the aviary in which they were main-

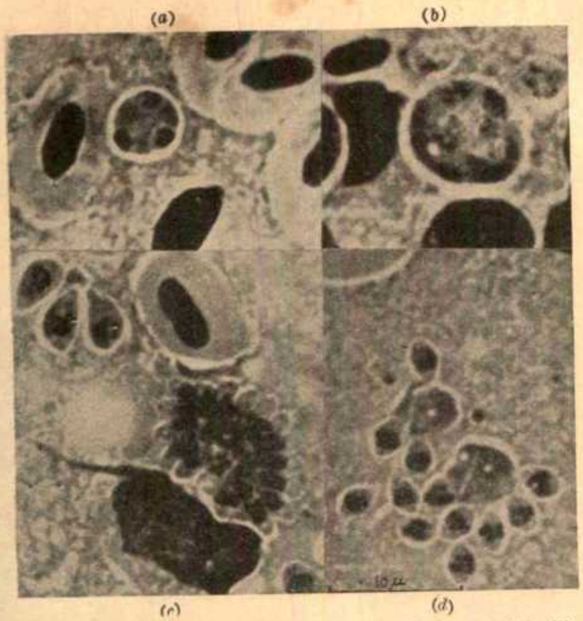

Fig. 1. (*a*) Early schizont of *Atoxoplasma* with three nuclei. (*b*) Schizont with ten nuclei. (*c*) Schizont, nearly mature, showing the peripheral distribution of the nuclei and finger-like protrusions of cytoplasm which form the merozoites. Compare size of merozoites with the normal *Atoxoplasma* seen in top left of same photomicrograph. (*d*) Mature schizont in process of splitting into merozoites; note residual cytoplasm

tained. Post-mortem examination of these birds revealed the spleens to be double their normal volume while the livers were enlarged, pale and frequently marbled in appearance. It was concluded that the tremendous numbers of atoxoplasms were responsible for the deaths.

A study of impression smears of spleen, liver and bone-marrow showed all stages of an undoubted schizogonic process of the parasite (Fig. 1, *a*–*d*). This occurs within the cells of the lymphoid–macrophage system, many of the schizonts becoming dislodged in the preparation of the smears. Up to 20–30 merozoites may be produced: these are substantially smaller than the normal atoxoplasm and possess a much more compact nucleus.

Atoxoplasma was passaged to canaries by the intraperitoneal inoculation of heavily infected, triturated sparrow tissues. Many of the infected canaries died, one with a very intense infection similar to that seen in the sparrows. The possibility of concomitant *Toxoplasma* infections being responsible for the sparrow and canary deaths was ruled out by the inoculation of mice, hamsters and guinea pigs, none of which became infected.

An apparent transmission of *Atoxoplasma* occurred when a canary was placed near another cage containing infected birds. As the only factor to account for this transmission was heavy infestation of the birds with 'red mite' (*Dermanyssus gallinae*) particular attention was focused on this ectoparasite.

Large numbers of mites from infected birds' cages were fed to a newly obtained canary. This bird was killed 14 days later and proved infected.

At present, attempts are being made to determine whether or not any development of *Atoxoplasma* takes place in the mites. So far it has only been possible to show that large numbers of the parasite can be found in crush smears of mites taken after feeding them on infected sparrows, but extended observations are necessary.

It seems likely that *Atoxoplasma* may be transmitted in Nature by mites. This suggestion is supported by the transmissions described above; also by the fact that *Dermanyssus gallinae* is commonly found in the nests of many wild birds (particularly sparrows) and young sparrows invariably become infected before they leave the nests.

The demonstration of a schizogonic phase of *Atoxoplasma* in the vertebrate host and the transmission of the parasite by mites now sharply differentiates *Atoxoplasma* from *Toxoplasma*.

A detailed account of these observations is to be published in the near future.

Added in proof. Since this communication was prepared, a number of naturally infected canaries have been found. Superficially this would appear to invalidate the experimental transmissions. As all canary breeders I have questioned admit to "inevitable presence of red-mite infestations in aviaries at some time or other", this ectoparasite must still remain highly suspect. The naturally infected canaries had been bred in outdoor aviaries, in the close vicinity of nesting sparrows.

Perfect and Imperfect Density Dependence in Population Dynamics

IN his recent article[1], Solomon has not made clear either my thesis or his reason for rejecting it. The thesis was developed in relation to my theory of natural control of insect populations for which a new classification of environmental factors was necessary[2,3]. Let me attempt to clarify.

An individual organism fulfils itself when it lives healthily, realizes its reproductive capacity fully, and dies of old age (senescence). Everything which helps or hinders fulfilment of the individual is the effective environment. Starting from Smith's[4] definition of a density-dependent factor, the effective environment may be classified as perfectly and imperfectly density-dependent factors and density-independent factors. There is only one perfectly density-dependent factor, intraspecific competition. The group named imperfectly density-dependent is comprised entirely of enemies (including competing species). Some enemies (for example, browsers, fruit eaters, etc.) come into the density-independent group of factors, a group which is otherwise well known as to its constituents. That is my position[2,3] very briefly.

In conversation and correspondence (October–December 1957) Solomon held, in substance, that since (1) intensity of intraspecific competition can be different for the same population number hence (2) this competition is not affected solely by numbers, that is, is not perfectly density-dependent. I argued that while (1) is correct, (2) is seen to be a *non-sequitur* as soon as it is realized that intraspecific competition is essentially a matter of environmental capacity. When intensity of competition is different for the same population number, this just means that environmental capacity is different. There is no getting away from the fact that for any given environmental capacity intraspecific competition is perfectly density-dependent. If the capacity alters, the curve of competition intensity changes in regard to the level of numbers for its origin and possibly changes in regard to its slope, but it does not cease to be a function solely of numbers. It should be added that alteration of environmental capacity can be absolute, that is, independent of the organisms concerned, as when weather favours or retards the growth of vegetation for food or shelter; or it can be relative, that is, due to modification of average individual needs brought about, for example, by weather increasing and decreasing activity, or by some change in age-distribution or genetical composition of the population[3]. Mr. Solomon did not counter the above argument to my satisfaction.

Solomon now says[1]: "I do not believe that *factors* perfectly dependent on density exist except at a high level of abstraction. In Nature, the actions of all factors are presumably variable and inexact." [The italics are mine.]

In that statement it is interesting to note (1) a plurality not present in my thesis (cp. "factors"); and (2) an indirect admission that I am correct in holding enemies to be at best imperfectly density-dependent factors. I would suggest also that the "high level of abstraction" has actually existed for a long time in the unwitting ascription of perfect density-dependence to enemy action as in Nicholson's popular theory of natural control of population.

It is also interesting to note Solomon's adherence to another abstraction, namely, the 'inverse' density-dependent factor. This factor was a tentative proposition by Howard and Fiske[5], of which, as Allee *et al.*[6] point out, Smith[4] "made little". The proposition is on a par with the erroneous idea prevailing until recently[2,3] that a density-independent factor killed a constant proportion of the population in Nature. I put it to Mr. Solomon that there is no field evidence of 'inverse' density-dependence which will stand up to stringent ecological and statistical analysis (and that includes so-called 'sexual isolation').

Again there seems to me little point in distinguishing between factors the density-dependent action of which is (1) immediate ('direct') or (2) delayed ('alternate') simply because enemy reproduction is not immediate. I think it more useful to regard delay in action as contributing to the imperfection I ascribe to the density-dependence of enemies.

I should go further than Varley[7] (though for different reasons) and say there is no advantage in adopting Solomon's classification of density-dependent factors.

A. Milne

[7] Varley, G. C., *Nature*, **181**, 1780 (1958).

I OBJECTED to Dr. Milne's proposed term "perfectly density-dependent" because neither intraspecific competition nor any other factor to be observed in the field is likely to preserve (in the words of his definition[1]) "an exact linear (or curvilinear) relationship between increasing action of the factor and increasing density of the species". The logic of his argument can be made clearer by re-stating it as follows. If all causes of variation were removed, there would be a simple and exactly maintained relationship between the intensity of intraspecific competition and the population density. Let us relegate all sources of variation to a category for which we shall borrow the term environmental capacity. Then we are left with a perfectly density-dependent factor, intraspecific competition.

I see no objection to this argument as an exercise in logic or as a step in the development of a simplified mathematical theory. I only wish to point out that the perfection achieved in this way bears little relationship to what we can expect to find in studying the dynamics of actual populations, and that therefore the term seems inappropriate for use by the practical ecologist. It should perhaps be added that, by a similar process of abstraction, the relationships expected to hold between a parasite or predator population and the density of its host can also be made to appear simple and regular, as in the mathematical theories, although imperfect in Milne's sense.

Milne's remark about Nicholson's theory refers to a point already dealt with by Varley[2] in these columns.

Milne objects to the idea of inverse factors because "there is no field evidence of 'inverse' density-dependence which will stand up to stringent ecological and statistical analysis". But since, unfortunately, we have very little field information of this quality on density relationships of any sort, we can scarcely attach special significance to the lack of it in this case.

As to "the erroneous idea prevailing until recently that a density-independent factor killed a constant proportion of the population in Nature", in fact the idea that the action of density-independent factors varies in intensity is, of course, neither new nor at all unfamiliar. It is true that Howard and Fiske[3] wrote of catastrophic factors that "the average percentage of destruction remains the same, no matter how abundant or how near to extinction the insect may have become", and Smith[4], in re-naming these factors 'density-independent', described them as "destroying a constant percentage regardless of the abundance of the insect". But it seems obvious that their intention was to argue that the percentage effect of density-independent factors did not vary in response to changes in population density, not that they necessarily produced a mortality-rate which did not vary in time. In a discussion[5] published nine years ago, I unhesitatingly adopted the former view, and have seen no protest on this score. Milne's claim implies that ecologists have hitherto believed that mortality due to weather factors is constant.

Although Milne sees no advantage in my proposed classification of density-relationships, some ecologists may do so. It has at least the advantage of making no assumptions about particular types of factors in advance of our knowledge of them. This discipline is likely to be valuable for some time to come, even if the categories I suggested are augmented, subdivided or replaced by others.

Association of Applied Biologists (in the Lecture Hall of the British Museum (Natural History), Cromwell Road, London, S.W.7), at 10.50 a.m.—Symposium on "Clubroot Disease".

Council for the Preservation of Rural Wales (at the Church House, Welshpool, Montgomeryshire), at 2.30 p.m.—Annual General Meeting. Speakers: The Lady Megan Lloyd George, LL.D., J.P., M.P., the Rt. Hon. Clement Davies, P.C., Q.C., M.P.

Royal Society of Medicine, Anæsthetics Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Prof. J. H. Burn: "The Pharmacological Investigation of Anæsthetic Drugs for Clinical Trial".

Institution of Electrical Engineers, Medical Electronics Discussion Group (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion Meeting on "Problems in the Measurement of Blood Flow". Opening Speakers: Dr. A. C. Dornhorst and Dr. D. A. McDonald.

Society of Dyers and Colourists, London Section (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Mr. S. M. Jaeckel and Mr. D. L. Munden: "Some Aspects of the Dyeing and Finishing of Fabrics Knitted from Bulky and Stretched Yarns".

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. A. Cohen: "Synthesis in the Ergot Alkaloid Field".

Royal Aeronautical Society (joint meeting with the Helicopter Association, at 4 Hamilton Place, London, W.1), at 7 p.m.—Dr. G. S. Hislop: "Development of the Fairey Rotodyne".

Saturday, November 8

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Prof. C. von Fürer Haimendorf: "Buddhist Society in the Himalayas".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant (with special qualifications in organic chemistry) in the Department of Chemistry—The Secretary, The University, Edinburgh (November 8).

Head (with a good honours degree and experience of teaching in an institution of higher education) of the Department of Science, Nigerian College of Arts, Science and Technology—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (November 10).

Lecturer in Radio-Astronomy—The Registrar, The University, Manchester 13 (November 10).

Senior Lecturer (with a good honours degree and teaching experience) in Applied Mathematics; and Lecturers (2) (with a good honours degree and teaching experience) in Mathematics at the Nigerian College of Arts, Science and Technology—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (November 10).

Assistant Lecturer in the Department of Pure Mathematics—The Registrar, University College of Wales, Aberystwyth (November 15).

Assistant Lecturer (with an honours degree from a recognized university and preferably previous teaching or research experience) **in Psychology** at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, November 15).

Leverhulme Student (with a postgraduate diploma in chemical engineering or equivalent qualifications) **in Chemical Engineering**—The Registrar, King's College (University of London), Strand, London, W.C.2 (November 17).

Senior Lecturer or **Lecturer in Physics**—The Registrar, The University, Manchester 13 (November 17).

Lecturer in the Department of Mathematical Physics—The Secretary, The University, Edinburgh (November 24).

Head (with a degree in applied mathematics) **of the Department of Mathematics and Physics**, Kumasi College of Technology—The Council for Overseas Colleges of Arts, Science and Technology, 12 Lincoln's Inn Fields, London, W.C.2 (November 25).

Chair of Mechanical Engineering—The Secretary, The Queen's University, Belfast (November 30).

Research Fellow in Heat Transfer, to pursue research into the mechanism of heat transfer from long pipes, carrying steam in the transition region from superheated to saturated—The Registrar, University College of Swansea, Singleton Park, Swansea (December 1).

Senior Lecturer in Mechanical Engineering—The Secretary, The Queen's University, Belfast (December 1).

Lecturer in Education at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 5)

Professor in Physiology at the University of Queensland, Australia.—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 15).

Lecturer and an **Assistant Lecturer in Genetics**—The Secretary of University Court, The University, Glasgow (December 31).

Director of the Commonwealth Bureau of Horticulture and Plantation Crops, East Malling Research Station, near Maidstone, Kent—The Secretary, Commonwealth Agricultural Bureaux, Farnham Royal, Bucks (January 31).

Assistant Lecturer, Grade B (with a degree or equivalent and preferably industrial and/or teaching experience), **in Telecommunications**, to teach up to the Final Certificate of the City and Guilds of London Institute and the R.T.E.B. Radio and Television Servicing Certificates—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

Assistant (preferably with experience of biochemical or other techniques in microbiology), for research on the mode of action of antituberculous drugs—The Secretary, Guy's Hospital Medical School, London, S.E.1.

Fellow in the Department of Chemistry, for fundamental research on electron resonance spectroscopy—The Registrar, The University, Birmingham 15.

Junior Bacteriologist, to assist in the investigation of intestinal disorders of newborn animals—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1.

Laboratory Assistant (age about 30–35, experience of anatomical and biological laboratory techniques, and preferably an elementary knowledge of photographic processes and/or histological procedures)—The Establishments Officer, Zoological Society of London, Regent's Park, London, N.W.1.

Lecturers (2) (graduates of a British university and preferably specialists in experimental microwave physics or theoretical metal physics) **in Physics**—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Professor (British subject with British university qualifications) **of Biochemistry** in the University of Teheran, Iran—The Director, Personnel Department, British Council, 65 Davies Street, London, W.1, quoting N.3(58).

Research Fellow (with a good research background and suitably qualified academically) **in Metallurgy or Solid State Physics** in the Department of Aircraft Materials—The Recorder, College of Aeronautics, Bletchley, Bucks.

Research Physicists (with a first- or good second-class honours degree) for (*a*) to exploit techniques for measuring flux and spectral distribution of neutrons from reactors and accelerators; and (*b*) to study and measure high energy (greater than 10 MeV.) radiations—The Group Recruitment Officer (1233/34), U.K.A.E.A., Atomic Energy Research Establishment, Harwell, Berks.

Technical Assistant in Electronics in the Isotopes Laboratory, for work which will involve the maintenance of routine counting equipment, as well as the designing and building of apparatus to research requirements—Joint Clerk to the University Court, Queen's College, Dundee.

WILD-BARFIELD LABORATORY MUFFLES

ENSURE PERFECT PERFORMANCE

This horizontal rectangular muffle is ideal for such purposes as incineration, burning off precipitates, and the heat-treatment of small samples of metal. The proportions have been fixed after careful examination of such laboratory needs. Temperature control by a hand-operated energy regulator type controller. Maximum recommended temperature — 1,000°C (1832°F). Wild-Barfield's great experience ensures perfect performance and a long trouble-free life. Full details on request.

THE AGRICULTURAL RESEARCH COUNCIL

THE report of the Agricultural Research Council for 1956–57* covers the first year of operations under the Agricultural Research Act, 1956, which made the Council directly responsible to Parliament and not to the Treasury for its expenditure on agricultural research. Under these new arrangements the Council has taken over responsibilities that the Ministry of Agriculture had in financing State-aided agricultural research centres in England and Wales. The total vote by Parliament to the Agricultural Research Fund for 1956–57 was £3,626,000, and this was allocated to a very wide range of research, much of it of a fundamental nature.

One very pleasing feature of the work is the substantial number of 'research units' which are set up in close association with universities and usually with the head of the university department as its honorary director. Men like Prof. F. G. Gregory, with his Research Institute of Plant Physiology at the Imperial College of Science and Technology, London, and Prof. K. Mather, with his Unit of Biometrical Genetics at Birmingham, are assisted by the provision of staff and facilities to develop research programmes which could not otherwise be undertaken. In addition, direct grants are given to universities to enable research on specific projects of shorter duration. Nearly every university in Great Britain is represented in this list, and virtually every science basic to agriculture is included. Then there are the research studentships and fellowships, numbering 75 in all, to promote the training of research workers, mainly in universities. By following such a policy not only is the Council safeguarding the supply of trained staff for the large State-aided or financed research institutes which are its main concern, but also it is helping in providing the stimulus of lively research at teaching centres.

The list of research institutes is a long and impressive one. At the head of the list is Rothamsted, which was once financed by a private endowment from its founder, Sir John Lawes. Now 90 per cent of its funds are provided by the Agricultural Research Fund. Plant breeding is very well catered for, and there are three major institutes concerned with this work, while there are other centres with plant breeding departments. Here, one detects a certain lack of balance, for considerably less emphasis is placed on animal breeding for, apart from poultry (which is well served), there is only one major organization concerned with this very important field. It is not suggested that plant breeding should receive less attention so that animals should receive more, but that animal-breeding studies should, in their own right, receive more help, for animal production constitutes the major part of total agricultural production in Great Britain. Though the beef industry is one of the most important branches of farming, apart from some reference to the genetics of beef and milk production in dual-purpose cattle at the University of Edinburgh and carcass-quality studies at Cambridge, there appears to be little concern for the future of the roast beef of England.

On the other hand, the dairy industry is well catered for with two large institutes at Reading and Ayr, and here again this emphasizes the need for the projected Meat Research Institute to co-ordinate and assist the limited amount of research which is being undertaken with meat animals.

Another major deficiency of immediate concern is the poverty of research into farm buildings. The Agricultural Research Council has a special committee on this, headed by the Council's chairman, but so far matters do not appear to have progressed much beyond the committee stage. The State, however, has committed itself to a very expensive farm improvement scheme ; but there is not the basic information on building design to ensure the thrift of housed stock or to secure a fuller economy of labour.

But one must not judge the work of the Council by such deficiencies, for there is so much that is good that has been achieved. There is the better understanding of husbandry control of internal parasites that has come out of the work of the Grassland Research Station at Hurley ; there is the Wye College contribution on MCPB to give a herbicide which does not injure clovers ; the new winter oat Powys that Aberystwyth has bred, and a dozen more instances of really valuable advances. Especially is this true on the veterinary side, where Britain preserves its long-established leadership. The value of this work in one field may be instanced by a quotation from the report on the Moredun Institute : "Not more than thirty years ago there were in Britain nineteen major diseases of the sheep, of which the causes were unknown. To-day, in eighteen of these diseases the cause has been demonstrated and in fourteen of them specific means for cure or prevention have been evolved". This is a fine record, and one would imagine that these advances in controlling sheep diseases alone have effected an annual saving more than sufficient to fund the whole cost of the Agricultural Research Council's work.

SCIENTIFIC DEVELOPMENT AND THE UNIVERSITIES

Technology and the Academics

An Essay on Universities and the Scientific Revolution. By Sir Eric Ashby. Pp. vii+118. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1958.) 15*s*. net.

THE substance of this book is the series of Ballard-Matthews Lectures which Sir Eric Ashby gave in the University College of North Wales at the beginning of this year. It is a fascinating book and a timely one. It is also a courageous book. The problems raised are set in a wide background and put forward in a way which must appeal to a far wider public than those who are more immediately concerned with their solution.

The writer's thesis is the split personality which exists in British universities to-day. He outlines the four functions which the universities are attempting to fulfil: their functions to train people for the professions, to act as a nursery for gentlemen, statesmen and administrators, to provide a centre for scholarship and research, and to serve as a staff college for technological experts and specialists. It is startling and, at the same time, refreshing to find an analysis of the functions of a university in such simple and down-to-earth terms. The problem is to reconcile these four different functions in one and the same institution. As one would expect, the writer draws frequently on biological analogy. "In social institutions as in living organisms form and function are inextricably bound together. If function changes then form must adapt itself or the organism—and the institution—will perish." Adaptation in the universities is, it is maintained, by no means complete, and form is not everywhere fitted to function.

The first three chapters of the book are devoted mainly to a description of the reasons why, and the manner in which, technology became a university function in Great Britain. There is an absorbing first chapter on the development of science in the continent of Europe, the reasons for lack of enthusiasm at that time in British universities (that is, Oxford, Cambridge and the Scottish universities) for scientific thought, though British scientists individually played a notable part in the development of science in the eighteenth and early nineteenth centuries. He traces the early developments in France, "the mother of organized research", the export of science across the Rhine but not across the Channel and then the development of the German universities and Technische Hochschulen. The second chapter is devoted to the much later development in Great Britain, the influences which brought about the changes in Oxford and Cambridge and the growth of university colleges. There are some stimulating, and perhaps controversial, thoughts on the results of the impact of science on the universities, their impetus to the growth of intellectual freedom, the democratization of the academic world, and the growth of a cosmopolitan and even international spirit in the universities. Ashby then comes to their adoption of technology and shows how the differences in our environment led not to a facsimile of the continental institutions but to something very different and probably more fundamentally sound. The reasons for the development of technology within university precincts, rather than in separate institutions, are of particular interest to-day when efforts are being made on the Continent and in the United States to broaden and strengthen technology by bringing it into closer contact, both for staff and students, with the pure science and the humanities, to the mutual benefit of all three.

The symptoms of schizophrenia are the basis of the concluding chapters and the diagnosis is an able one. Finally, one cannot but refer to the delight of reading a book of such fundamental importance which is written in so engaging a way; its literary style, as one expects from Sir Eric Ashby, is impeccable. While there is an exceptional awareness of what has gone on and is going on both in Great Britain and overseas, there is a complete absence of that ostentation which too often accompanies so great a wealth of knowledge.

TECHNIQUES IN SOCIOLOGY

Survey Methods in Social Investigation

By C. A. Moser. (Heinemann Books on Sociology.) Pp. xiii+352. (London: William Heinemann, Ltd., 1958.) 35*s*. net.

IT is made plain in the introductory chapter of this book that the techniques with which it deals are more relevant to 'extensive' rather than 'intensive' inquiries; that is to say, it is primarily concerned with official surveys of the kind conducted by the Central Office of Information, market and opinion research, and the large-scale operations of social scientists. This is also evident from the fact that approximately a third of the book is devoted to the application of sampling methods, and a discussion of the problems that arise in the use of samples.

Although the book must, therefore, be regarded as restricted in its scope, despite its title, the introductory section also contains a discussion of the general nature of social surveys; it also ends with a broader treatment of methods of collecting information, including the use of documents, questionnaires, and interviewing, and a discussion of the methods of processing the data so obtained.

So far as the nature of social surveys is concerned, Mr. Moser points out very wisely that fact-collecting is no substitute for serious thought, remarking that "it is the ill-considered launching of surveys, leading to the waste of much time and money and the accumulation (often) of unwanted data, that has given rise to the scepticism with which some sociologists regard 'door-knocking' research." "It is no good," he adds, "blindly to apply the formal standardized methods generally used in official or market research enquiries, to many of the more complex problems in which sociologists are interested." This is all too true, but the comment would have been all the more valuable if it had been based on actual examples, of which there are many. Sociologists must be helped to learn from their mistakes, painful as the experience may be.

The main section of the book on sampling methods provides a useful text on which those actively engaged on large-scale inquiries can rely. So far as the collection of the raw data is concerned, on the accuracy of which the value of every survey is ultimately dependent, Mr. Moser is entirely correct in saying that problems arise which are different in kind, rather than in degree, from those arising out of sampling. This is an obvious point. Much more attention should be directed to it rather than, for example, to the more elementary processes of sampling which are apt to be explained and discussed *ad nauseam*.

As Mr. Moser puts it, "our knowledge of data collection is, by comparison, primitive . . . One part of the survey process is tackled by a tool of high precision that makes accurate estimates of errors possible, while in the other parts errors of generally unknown proportions subsist". The impression is thus given that the high degree of accuracy with which the results of large-scale surveys are frequently stated may be misleading, perhaps very misleading indeed. This is probably true. Much more research into this difficult problem is required.

T. S. Simey

PLANTS OF THE FARM

Agricultural Botany

By Dr. N. T. Gill and K. C. Vear. Pp. viii+636. (London: Gerald Duckworth and Co., Ltd., 1958.) 63*s*. net.

Although botany began as the collection of information about economic and medicinal plants, the modern teaching subject of agricultural botany emerged as an eclectic version of 'pure' botany, based on economic examples. This was the plan of the late Prof. Percival's well-known textbook, even up to its last edition in 1936. Since the turn of the century, however, several fields of endeavour have developed a structure and outlook of their own. Thus, plant pathology and plant breeding are to-day largely independent disciplines, recognizably distinct in their methods of thought and action from mycology or genetics. Comparable trends are evident in crop physiology. The subject as a whole seems to be developing a coherent unity along lines indicated in part by Vavilov, and based upon the ecological connexions between its parts. This may well lead agricultural botany to a relationship to pure botany not unlike that of engineering to physics.

Against this background the present work is distinctly disappointing. It consists of a reasonably detailed and well-illustrated conspectus, on a taxonomic basis, of the agricultural and horticultural plants and weeds of temperate regions, with some tropical crop species added (400 pages), sandwiched between very much less satisfactory and far less well-illustrated accounts of plant breeding and plant diseases (about 100 pages each). Its stated aim is to meet the requirements of agricultural diploma and pass-degree students; but it would seem that many of them will find the systematic part more than adequate for their needs, while remaining unsatisfied by the remainder.

More serious than this lack of balance is the almost complete absence of any account of the extensive modern work on the physiology and ecology of crops and weeds. Yield is usually the most important characteristic of economic plants. The analysis of plant growth and yield is consequently an essential part of the contribution botany can make to farming; indeed, it can be thought of as the theoretical basis of agriculture. Yet the outstanding advances of the past thirty years in the study of the crop as an assemblage of growing and competing plants, continuously influenced by varying environmental factors, is not reflected in these pages.

The principal merit of the book, then, lies in the systematic description of agricultural plants, which fills a need by bringing together a useful body of fairly up-to-date information not elsewhere available in one volume. For this the work may be recommended, though the price may seem unduly high to some.

A. H. Bunting

". . . THE EAST WIND BROUGHT THE LOCUSTS"

Insect Migration

By Dr. C. B. Williams. (The New Naturalist: a Survey of British Natural History.) Pp. xiii+235+24 plates. (London: William Collins, Sons and Co., Ltd., 1958.) 30*s*. net.

Among British entomologists who have worked in the tropics within the past generation, there are probably not many for whom a visit to Rothamsted has not provided stimulation, together with an injunction from Dr. C. B. Williams to keep a look-out for butterfly migration. All who heeded his injunction, and all who know his comprehensive and critical book on this subject, published in 1930, will welcome this entertaining and copiously illustrated addition to the admirable "New Naturalist" series.

The present book, however, is perhaps one to arouse interest rather than to satisfy it. A serious reader, seeking to follow up some tantalizing allusion, and undaunted by an absence of references in the text, is still likely to be frustrated by the slim bibliography, with its sixteen titles since 1942, out of the several hundred of which Dr. Williams tells him—and makes use. Moreover, in the introduction the author makes a distinction between deliberate migration and drift on the wind, and he defines migration as "a continued movement in a more or less definite direction, in which both movement and direction are under the control of the animal concerned". But he does not say a great deal about the extent to which the material he presents satisfies his own definition: some species appear to be described as migrants mainly because they are often seen a long way outside their breeding areas—without much consideration of any contribution which may be made to these geographical displacements by the winds at the time.

Dr. Williams's editors suggest that his book may almost be regarded as a world detective story; and he tells how, for locusts, the original case for deliberate long-range migration appears to have collapsed under the evidence of synoptic meteorology. But in this book his own approach sometimes suggests the compiler of criminological statistics rather than the detective. Thus, eleven pages of tables, and four figures, demonstrate that a number of species of butterflies and moths have been recorded in Britain more frequently in some years than in others; but there is little examination of any possibility of an association of environmental conditions with such occurrences and their fluctuations—which is the more disappointing in view of Dr. Williams's own pioneer work on the effects of weather on insect populations.

But his readers, like the followers of the best detectives, will look forward to meeting him again as he deals with new evidence. Urquhart has reported flights of up to 2,000 miles by individual marked Monarch butterflies in North America: details of such flights, which are still awaited, and of the wind-systems encountered during them, may perhaps provide the first rigorous demonstration of long-range insect migration in the strict sense of Dr. Williams's definition. R. C. Rainey

HYDROGEN ION CONCENTRATION AND ACTIVITY

A Dictionary of pH Applications

By R. S. Evans. Pp. viii+78+xviii. (London: The Herbert Publishing Company, Ltd., 1957.) 10*s.* 6*d.* net.

The Book of pH

A simple and complete Description of the Theory and the Practice of the Measurement of *p*H as applied to Science and Industry. By R. B. Webber. Pp. 111. (London: George Newnes, Ltd., 1957.) 30*s.* net.

That two books on the applications of *p*H to industrial processes should appear together is a remarkable coincidence. Mr. R. S. Evans's book is sponsored by W. G. Pye and Co., Ltd., of Cambridge, and Mr. R. B. Webber's by Tintometer, Ltd., of Salisbury. Both books are designed to impress the industrialist, who, incidentally, is assumed to have no chemical knowledge, of the great importance that *p*H data may be to him and yet how very simple it is to make *p*H measurements. In the first, it is stated that glass-electrode *p*H meters are rapidly replacing colorimetric methods, which are not even described, while in the second, colorimetric and electrometric methods are very simply discussed, but it is emphasized that colorimetric methods are very much easier to operate, especially if use is made of the Lovibond comparator and Nessleriser in conjunction with permanent colour standards (of glass) which correspond with the colours of indicators at specified *p*H values, and which are mounted in a rotating disk to facilitate comparison. To estimate the *p*H of unbuffered, or poorly buffered, solutions, when it is essential to use as low a concentration of indicator as possible, the Nessleriser is used. In this method it is assumed that the effect of the *p*H of the indicator itself is rendered negligible. It would have been better if the isohydric indicator method had been given, but perhaps the reason for its omission is to be found in the assertion made on p. 81 that "the operators need not be particularly intelligent or skilful" to carry out colorimetric determinations.

Explaining the meaning of *p*H to the uninitiated is obviously something of a problem. Evans is content to leave the problem by saying that the *p*H value "may loosely be defined as a measure of acidity or alkalinity", whereas Webber starts off by stating that "the concept of *p*H is fundamentally very simple" and likens the *p*H scale to the centigrade scale of temperature, each number of the *p*H scale having "an exact meaning". Later, he declares that "the *p*H story is not an over-simple one". In the middle of the book he gives the mathematical expression which relates *p*H with hydrogen ion concentration, but towards the end he attempts to explain that it would be better to substitute activity for concentration. It must be comforting to the reader to be told that whichever view is accepted it will only make a difference in the observed *p*H value, within the *p*H range 2–12, of ± 0·02 *p*H unit.

Webber includes a couple of pages on measuring the hydrogen ion activity of non-aqueous solutions and refers to the *c*G scale which J. B. Conant introduced many years ago but which has not been seriously regarded. Such a discussion might be considered to be out of place in a book of this type.

Both volumes might be considered to have fulfilled a need, but that of Webber has done so more effectively. H. T. S. Britton

APPLIED ACOUSTICS

Acoustics, Noise, and Buildings

By P. H. Parkin and H. R. Humphreys. Pp. 331. (London: Faber and Faber, Ltd., 1958.) 70*s.* net.

In post-war Britain classical physics has been much neglected because of the great attractions of nuclear physics. Consequently, activity in Great Britain on the subject of acoustics is on a very small scale, although slightly more is now done than before the War, when the subject was practically ignored. In the United States and on the continent of Europe, on the other hand, much more work is done, and considerable effort goes into research and investigation. It is therefore not surprising that, although several text-books have been published in Europe or in America and some of the European books have been translated into English, the last important book was "Acoustics" by the late Alexander Wood, published in 1940. Messrs. Parkin and Humphreys are therefore to be congratulated on writing the present volume, which fills a long-felt want.

This book is not intended to be a text-book but a survey of the subject for those not qualified in physics, such as architects, engineers and others who may be interested in acquiring a reasonable knowledge. The first two chapters on the "Nature of Sound" and "The Behaviour of Sound in Rooms" are in elementary terms to act as an introduction to the subject. Chapter 3 describes "The Design of Rooms for Speech" and should be of great value to individuals interested in the improvement of the acoustics of theatres, lecture rooms, classrooms and similar buildings. Chapter 4 describes a much more specialized field, "The Design of Rooms for Music". The description of the various factors affecting design is very lucid, and most of the difficulties are described in considerable detail. Greater emphasis might, however, with advantage have been placed on the fact that the final criterion for such rooms is æsthetic and that personal opinion plays a large part in the final judgment. Chapter 5, "The Design of Studios", describes the design of studios for broadcasting, which is a very specialized field indeed.

Another feature of post-war civilization seems to be the absence of the orator capable of addressing a large audience without assistance from electroacoustic devices. 'Public address' has consequently become firmly established even in quite small auditoria. Chapter 6, "The Design of High Quality Speech-Reinforcement Systems", is therefore a very valuable contribution and is particularly interesting for its description of the methods used for speech-reinforcement in very large cathedrals such as St. Paul's and Salisbury. In such enormous buildings with very long reverberation times it has never been possible for the congregation to hear the service properly. In these circumstances, speech-reinforcement systems are the only solution. In the case of very large arenas, speech-reinforcement is also essential. It is to be hoped that the designers of speech-reinforcement installations, which up to the present have been extremely unsatisfactory except as an emulation of Donald Duck, may profit by the details given in this book.

Almost half the book, commencing at Chapter 7, is given up to the problems of noise, which is one of the most pressing problems in modern times. Chapter 7 describes various types of noise and their effects, while Chapter 8 gives a detailed description, in simple terms, of "Sound Insulation and Noise Control Practice" in all types of building. The details of "Sound Measurement and Calculation" are given in Chapter 9. Chapter 10 provides details of "Criteria for Sound Insulation and Noise Control", which is a very useful summary of the present position.

This book is well written and should prove of great value as a general survey of the subject. In several places where differences of opinion are known to exist, the authors might with advantage have indicated the regions of controversy. This is particularly noticeable in the chapter on "Sound Measurement and Calculation", some parts of which are the subject of argument at international conferences. The value of the book might perhaps have been increased, without appreciable increase of effort on the part of the authors, by providing references to the considerable literature in this field, since this would make it easy for an interested reader to follow up any particular problem on which he requires more information.

T. SOMERVILLE

THEORY AND APPLICATION OF INTEGRAL EQUATIONS

Integral Equations

By Prof. F. G. Tricomi. (Pure and Applied Mathematics: a Series of Texts and Monographs, Vol. 5.) Pp. viii+238. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 7 dollars.

Integral Equations and their Applications to Certain Problems in Mechanics, Mathematical Physics and Technology

By S. G. Mikhlin. Translated from the Russian by A. H. Armstrong. (International Series of Monographs on Pure and Applied Mathematics, Vol. 4.) Pp. xii+338. (London and New York: Pergamon Press, 1957.) 80*s.* net.

THE systematic study of integral equations was stimulated about 1900 by the somewhat sensational work of Fredholm in providing a proof of Dirichlet's principle asserting the existence of a solution of Laplace's equation under given boundary conditions. The wealth of ideas in Volterra's pioneer work began to be appreciated; and by 1908 or so the main lines of the classical theory had been laid down, with major contributions from Hilbert and Schmidt. The linear Fredholm and Volterra equation involves a term of the type:

$$\int K(x,y)\,\varphi\,(y)\,\mathrm{d}y$$

where integration is over a constant range in the Fredholm equation, and from 0 to x in the Volterra equation, φ is the unknown, and K is a given function, the kernel. The method of successive approximation can be used to obtain formal solutions, as infinite power series in a parameter λ; but in the Fredholm case, the series does not necessarily converge for all λ, and Fredholm's great contribution was to replace the series by the quotient of two integral functions of λ. When the kernel is symmetric, $K(x,y) = K(y,x)$, connexion with orthogonal systems of functions is almost immediate, and leads to the Hilbert–Schmidt theory. If the kernel is of the form $H(x,y)/(x-y)^a$, so that the integral must be defined as a 'principal value', the equation is said to be singular, as are many of the equations which turn up naturally in applications, and we owe to Carleman the origins of two methods of coping with such equations. Nonlinear equations have also come recently into prominence again, though Schmidt began their investigation some fifty years ago.

All this theory is set out beautifully by Tricomi, in a most readable book. The material is deliberately restricted to the classical theory, but there are numerous references to guide the reader to further work on the theory and to the wide field of recent applications. Great care has been taken with the presentation; the reader will require only a sound knowledge of elementary analysis. An acquaintance with the Lebesgue integral is desirable, since the main conditions on the kernel is simply that the two-variable integral of $|K|^2$ shall be bounded, but even this knowledge is not absolutely essential. Of introductions in English, French or German, this seems to me the most attractive.

Linguistic difficulties have not entirely concealed the fact that in recent years great progress in the application of integral equations to physical problems has been made by Russian mathematicians, particularly by those centred at Tiflis. Two recent translations of books by Muskhelishvili, on elasticity and on singular integral equations, have helped to make this work accessible, and now this translation of the second edition of Mikhlin's book has added to our knowledge. It is in two parts: the first 130 pages cover much the same ground as does Tricomi's book, more concisely and with slightly more demands on the reader. The remaining 200 pages are devoted to applications, starting from the basic Dirichlet principle, and concerned chiefly with elasticity, hydrodynamics and aerodynamics. Here, of course, it is necessary that the reader should have a sound knowledge of the fundamental principles of these topics, such as a good honours degree student should possess. The problems are culled from a wide field, but are mainly one-dimensional or two-dimensional; the author remarks that the accusation of ineffectiveness sometimes levelled at integral equations is not without justification when problems in three dimensions are involved; here, no doubt, is a field for further research.

This systematic exploitation of a powerful method is most welcome. The translation reads smoothly almost everywhere; but there are some references in the text (for example, pp. 234 and 264) to items which do not appear in the bibliography.

T. A. A. BROADBENT

UNESCO HOUSE, PARIS

ON the architects of to-day rests the responsibility of designing the heritage of to-morrow. But few architects in any era can have faced a task so onerous as the planning of the Unesco headquarters in Paris—an edifice that at one and the same time had to embody the spirit of modernism inherent in the United Nations Educational, Scientific and Cultural Organization, provide a functional base for its activities and blend with neighbouring buildings that had already spanned the centuries. That this has been accomplished is due to three internationally eminent architects, Marcel Breuer (United States), Pier Nervi (Italy), and Bernard Zehrfuss (France), who prepared the original plans, and a consultative panel consisting of Lucio Costa (Brazil), Walter Gropius (United States), Charles Le Corbusier (France), Sven Markelius (Sweden), and Ernesto Rogers (Italy), who approved them. Eero Saarinen (United States) also acted in an advisory capacity, and Eugene Callison (United States) supervised the building operations.

The Unesco headquarters, which was formally opened on November 3, is made up of three buildings. The most dominating of these is the Y-shaped seven-storied secretariat on the Place de Fontenoy. Viewed from the Eiffel Tower—which in its time had to pass through periods of acute criticism, ardent admiration and strong dislike before being accepted as a landmark of the great city—the frontage of the secretariat completes a semi-circle with a French ministerial building and combines to provide an effective background for the eighteenth-century Ecole Militaire.

Though it complements the surroundings so beautifully, the new building is still strikingly modern. Mounted on up-thrusting *pilotis* which give an even greater impression of height than its actual 94 ft., it bears the same relationship to its brick and stone companions as a jet airliner has to its bi-plane predecessors.

Six hundred offices are accommodated in the building, spreading out from the central point of the Y. While, on the exterior, the windows, numbering more than a thousand with a glass area of some 72,981 sq. ft., give the building a shimmering appearance, in the rooms the light is equally distributed with a clarity that reduces the need for artificial lighting to a minimum even on the dullest days.

The conference building, which is connected with the secretariat by an impressive hallway, owes its main impact to its fluted concrete walls and 'butterfly' roof covered in copper. Here in a deceptively small area (35,327 sq. ft.) are housed the main conference halls and committee rooms, including the Plenary Hall with accommodation for almost a thousand people, a Main Commission Room with 270 seats at tables for delegates and observers and 77 seats for the public, an Executive Board Room which can also be used by one of the large commissions and five smaller committee rooms with seating accommodation

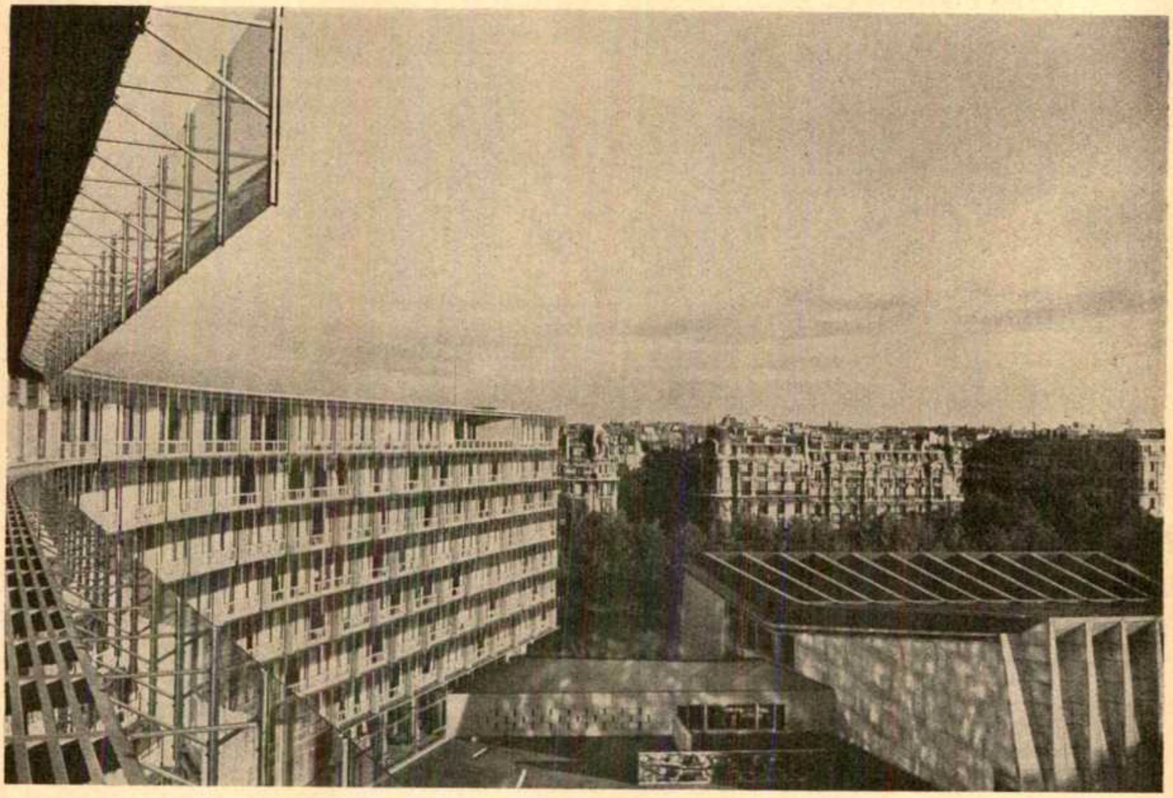

Fig. 1. Unesco House, Paris. Façade in Avenue Suffren

Photo: Unesco–Berretty

fees, materials, the installation of contributions from Member States, etc., they commissioned the following works of art: Paintings by Afro (Italy), Appel (Netherlands; Fig. 3), Matta (Chile), and a photographic panel by Brassai (France) for the lounge, restaurant and cafeteria of the seventh floor; a mural by Picasso (Spain) for the wall in the delegates' hall and a fresco by Tamayo (Mexico) for the commission room; a bronze haut relief by Arp (France) for the outside Library wall and for the grounds an eye-catching mobile by Calder (United States), a massive travertine figure by Moore (United Kingdom) and two ceramics designed by Miro and executed in co-operation with Artigas (Spain). Noguchi was entrusted with the task of designing a garden in the Japanese style, for which the Japanese Government sent stones and plants.

No attempt has been made to build a monumental pile dedicated to posterity. This is a strictly utilitarian setting for a working organization, and Unesco, while appreciating to the full the practical facilities it offers, still takes greater pride in being party to the establishment of a school, no matter how small, the opening of a library or the equipping of a laboratory in pursuance of its main aim of peace through universal understanding.

HEALTH AND SAFETY IN THE FIELD OF NUCLEAR ENERGY

THAT the development of atomic energy involves important contributions from a wide range of disciplines is generally accepted. This is true also in respect of the more limited field of the health and safety aspects and was well illustrated in the second United Nations International Conference on the Peaceful Uses of Atomic Energy held in Geneva in September, where some 170 papers were contributed on subjects either directly concerned with, or closely relevant to, the problems of radiation safety. The time available, however, allowed only a small number of these papers to be read and discussed. The progress in biology has been reported in a previous article (see *Nature*, October 25, p. 1118), and, although reports continue to be received of reversible biological response for exceedingly small doses of ionizing radiation, the evidence at Geneva tended to support the basic levels currently adopted for permissible occupational exposure.

Control of Occupational Exposure

Several important papers gave factual information concerning the doses experienced in the atomic energy work in a number of countries having large or small atomic energy projects. One paper, from Canada, showed that the recent reduction in the permissible mean annual dose from 15 r. per annum to 5 r. per annum had been fairly successfully followed in the occupational exposures incurred. Some of the papers, such as one from Great Britain, reported not only external radiation doses but also the control of internally assimilated isotopes, air and surface contamination, urine data, and the instances where contaminated wounds had been dealt with. Another paper of considerable interest summarized experience of radiation exposure in a number of industrial factories, the work of which involved exposure to ionizing radiation; it was emphasized that in most instances radiation protection in such factories has to be achieved with far fewer protection personnel than is considered necessary in atomic energy plants. A further important paper from Canada described recent experiences in the protection of health in uranium mining. Ever since pre-war days, when a high incidence of occupational bronchial carcinoma was observed as a result of long periods of work in certain uranium mines, the subject of the protection of uranium miners has been of considerable concern. The Canadian paper indicated how the very real difficulties of good radiological control have been met in Canadian mines.

A further aspect of operational experience was shown by many papers dealing with the design of plant and equipment for safety, and an excellent example was a description in an American paper of the extraordinarily complex installation utilized for the processing of high-activity alpha-active materials in chemical and metallurgical procedures. Such installations represent heavy capital investment devoted essentially to providing virtually a guarantee of radiation safety in handling these highly toxic materials.

Control of Environmental Hazards

One technical session was devoted to this subject, on which fifty-seven papers had been contributed. The papers included a comprehensive review of the control of environmental hazard around the Hanford Plant in the United States, and also a paper from Great Britain giving the detailed radioactivity measurements on biological materials in the environment, such as milk, herbage and crops, following the nuclear reactor accident at Windscale in October 1957. (A brief synopsis of the Windscale data was presented in articles in *Nature* of September 6, p. 627.) In this session also a few papers dealt with the important subject of the fate of radioactive materials in soils and the transport through the soil – plant – animal food-chain. Other papers on this subject appeared in a further session on the uses of radioisotopes in agriculture. Problems of the discharge of liquid wastes were also covered, and included a report from Great Britain on experience in discharging large-volume dilute wastes to coastal waters. A study by the U.S.S.R. of the rate of turn-over of water in deep-water ocean depressions showed that the previous estimates of the time taken for water in these depressions to exchange with surface waters had perhaps been over-estimated, and the Russian report, which covered many of the known ocean-deeps, concluded that the disposal of very large amounts of activity in such depressions would be likely to lead to hazard.

The World Meteorological Organization presented a survey showing the importance of meteorology to safety problems in atomic energy, not only in the obvious instances of a reactor accident involving airborne release but also under normal operating conditions. In various sessions of the Conference

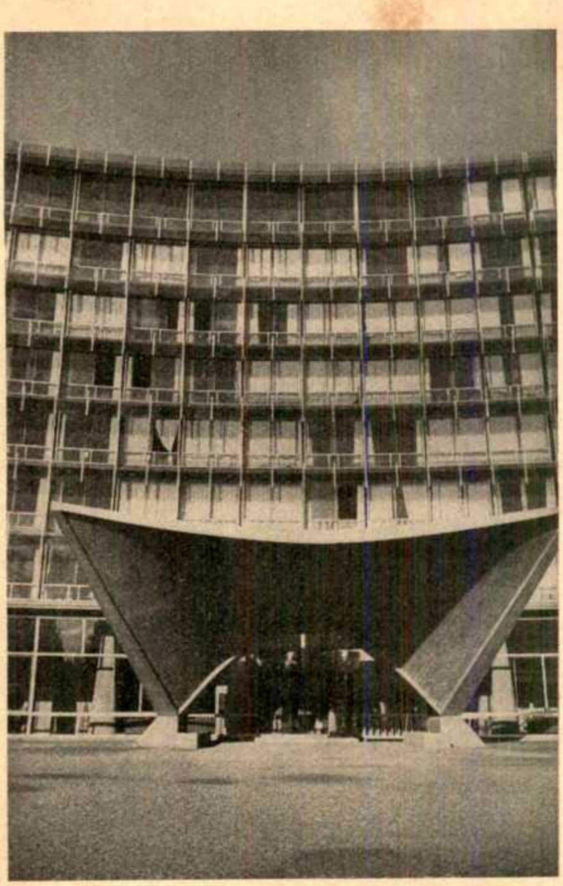

Photo: Unesco–Berretty

Fig. 2. Unesco House. Entrance from Avenue Suffren

ranging from 25 to 45. A special hall for international non-governmental organizations has also been provided along with ten offices and a Press room.

The permanent delegations to Unesco have been given offices in the third building, which follows the same exterior design as the secretariat building.

That these buildings should be constructed of the most modern—and cheapest—building material, namely, reinforced concrete, was not purely a budgetary decision. The limitation of funds (the ceiling was 9,010,000 dollars financed by interest-free loans from the French Government) imposed a certain degree of economy, but at the same time it was felt that the plasticity of concrete would give the desired freedom of architectural form and also be in keeping with the Organization's desire for functional simplicity.

The result is a pleasant contrast achieved by the juxtaposition of rough-surfaced concrete with Roman travertine and Brittany granite, the tone values being heightened by judicious use of wood for the window casings and other strappings. Great imagination has been used in the exploitation of the decorative worth of these construction materials, and even the concrete *pilotis* completely unadorned in themselves have a grace and force reminiscent of the pillars of ancient Greek temples.

But it is in the conference building that the extreme versatility of concrete is seen to best advantage. Here the fluting of the walls—fold after fold in wide corrugations—which adds so greatly to the æsthetic appearance, also has the practical result of ensuring perfect acoustics for the conference chambers. Similar unusual effects have been obtained by a fire staircase of pre-fabricated concrete blocks that winds its way in a spiral up one of the wings and by the canopy composed of two curved concrete surfaces that gives a dramatic quality to the doorway facing Avenue Suffren (Fig. 2).

An important part in making the headquarters what they are to-day is due to the Member States of Unesco. Engineers, furniture designers, electricians, office specialists, sound technicians, and industrial experts from ten countries have given an aura of internationalism to the most utilitarian objects, and in fulfilment of contracts workmen and equipment have come from Belgium, Czechoslovakia, the Federal Republic of Germany, France, Italy, Norway, the Netherlands, Switzerland, the United Kingdom and the United States.

In addition, thirteen countries undertook to present decorations and fittings for various parts of the buildings. Five of them, Denmark, France, the Federal Republic of Germany, Italy and Switzerland furnished committee rooms each demonstrating artistic trends in their own countries. The modern decor of the executive board room was a gift of the International Council of the Museum of Modern Art of New York made on behalf of the Government and people of the United States. The hall for the international non-governmental organizations was furnished by Czechoslovakia and the Press Room and Library by the Netherlands and Sweden respectively. The offices of the chairman and secretariat of the executive board are a gift of the United Kingdom and the office of the Director General is contributed by Belgium. The equipment and furnishings for the reception office, lobbies and gift-shop have been provided by Canada, Finland and Norway.

From the time the first line was drawn on the draughtsman's board it was recognized that contemporary art should be represented in these buildings. It was also realized that its selection would present considerable difficulties. So an advisory panel of art authorities, supplemented by members of the Architects Committee, was appointed to suggest appropriate artists. The panel consisted of H.E. Mr. C. Parra Perez (Venezuela), Mr. Georges Salles (France), Mr. Shahid Suhrawardy (Pakistan), and Sir Herbert Read (United Kingdom). With an allocation of 191,000 dollars, which had to cover artists'

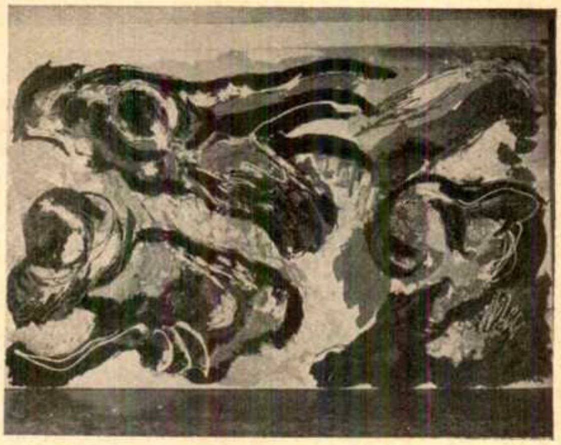

Photo: Unesco–Pablo Volta

Fig. 3. Painting by Appel on the restaurant wall (2·8 m. × 4·2 m.)

there were also several other papers dealing in some detail with each of these aspects.

Radiation Measurement and Dosimetry

Many of the papers concerned with radiation measurement were devoted to the use of gamma spectrometry. From the varied applications of this technique in the control of radiation hazards it is clear that it represents a most important advance. The application of the gamma spectrometric method to the measurement of gamma-radioactivity and beta-radioactivity (by bremsstrahlung) in the human body is now well known, and several papers showed the great value and promise of this technique. A further important application described in a paper from the United States was the use of this technique to measure traces of plutonium contamination in skin wounds and, in certain circumstances, a sensitivity of 4×10^{-5} microcurie of plutonium was attainable. The method offers an immense advantage in that the plutonium can be detected readily at depths in the skin far greater than the range of alpha-particles. The usefulness of the scintillation counting of alpha-activity was shown to good effect in a paper by Prof. W. V. Mayneord from Great Britain reporting direct measurement of the radium and thorium activities occurring naturally in human bone ash.

Progress was also noticeable in the dosimetry of airborne radioactive dust and the decay products of thoron and radon, the monitoring of which has presented considerable difficulties in the past. A paper from the U.S.S.R. by Baranov reported a useful application for health purposes of the $(n,2n)$ activation of carbon with the production of carbon-11 as a means of measuring fast-neutron fluxes in the energy-range exceeding 20 MeV.

Reactor Safety

Two technical sessions were devoted to this topic, on which about twenty-five papers had been contributed; these indicated substantial progress in this important subject. At the first International Conference in 1955 we had a report of experiments on a simple uranium – water reactor which was tested to destruction by power surges. At the present Conference we had reports on the theoretical and experimental investigation of reactor transients in full-scale power reactors. The development of experimental methods in this subject is advancing, so that we shall no longer have to rely so heavily in the future on unsupported calculations concerning safety in reactor kinetics.

Another important aspect of reactor safety in which there seems to be considerable progress is in regard to containment. Apart from reports from Sweden and Norway on novel underground containment for reactors, there appears to be a trend towards very strong compact enclosures which can give a considerable degree of guaranteed containment, and containment designs involving protection against shock-waves and missiles arising from fast-reactor 'runaway' were described from the United States. Indeed, it seems that, when the technology of the design and of the statistical testing of reactor enclosures (possibly on the model scale) has advanced somewhat further, we may well be in a position to tolerate nuclear reactors in heavily populated areas.

Several papers were again concerned with the evaluation of the accidental release of radioactivity from a reactor, and, while for many of the radiological effects the acceptable levels under accident conditions are in reasonable agreement, there appears to be considerable disparity with regard to acceptable emergency exposure of the thyroid; levels of 1,500 and 2,000 rad were suggested in some of the papers, whereas in the accident at Windscale the limiting level of milk contamination actually used corresponds to a thyroid dose of about 10 rad.

Some of the most valuable discussions at Geneva took place in a number of informal sessions in which specialists from several countries were able to meet and have free discussion on some of the more important problems in their particular spheres. One of the great values of the informal sessions was that spontaneous discussion could take place without the necessity for questions to be written down and handed up to the chairman in advance of the discussion period. One such session was devoted to problems of reactor safety, and included, among the introductory talks, one by Academician A. P. Aleksandrov on "Reactor Safety in the U.S.S.R." It was notable that the Russians tended to rely on design of control systems and on remote location rather than on containment to achieve safety, whereas other countries considered provision of satisfactory containment a necessary feature.

A further important informal session was devoted to criticality safety, and included an informal report of experience in a criticality accident at Oak Ridge in June of this year. Although a few persons were exposed to heavy doses of neutron and gamma-radiation ranging up to about 400 rem, the exposures were not lethal. Descriptions of events like this are extremely important in providing lessons for safety in design and operation of criticality facilities and, indeed, of nuclear reactors in general.

The general impression gained from a study of the large number of papers presented on subjects related to health and safety was that substantial progress is being made on many aspects of this important subject. It is considered exceptionally valuable that several countries had thought fit to report frankly their experience on radiation exposure both in regard to workers in their plants and to the environmental hazards of their operations. It is to be hoped that more countries will provide this kind of data in the future. A second important conclusion is that the standard of safety achieved is very high. It seems that the emphasis which has been placed on health and safety in the past has borne fruit, especially in regard to the amount of money which it is now accepted must be devoted to securing an exceptionally high degree of safety in nuclear reactors and plants. A further satisfactory feature of the reports presented at the Conference was the great strides which have been made in the techniques of measurement of radiations, especially for the purpose of health control. On the sensitive subject of radioactive wastes, there appeared to be universal recognition of the principle that the safety of any procedure for the disposal of radioactive materials, whether as liquid effluent or as gaseous activity to the atmosphere (which in the case of the noble gases may be difficult to avoid), must be demonstrated by comprehensive monitoring by the operating agency. This is a principle which might well be extended in other industries.

GRAPHITIZATION AND PLASTIC DEFORMATION OF DIAMOND

By DR. M. SEAL

Research Laboratory for the Physics and Chemistry of Solids,
Department of Physics, University of Cambridge

IT is well known that diamond is at normal pressures the thermodynamically unstable form of carbon, and that diamonds heated to a sufficiently high temperature change into graphite. A study has been made of this change, and two important results have been obtained. These are, first, that the change occurs via an intermediate structure of carbon atoms, and secondly, that plastic deformation of diamond can occur at 1,800° C. under the stresses set up by an expanding nucleus of graphitization.

In this investigation two types of diamond specimen were used—a fine powder of 0–1μ particle size, and large single crystals of up to a few millimetres across. The specimens were placed in crucibles of hard pure graphite and were heated in a vacuum of about 10^{-4} mm. mercury in an electric resistance furnace to various temperatures for 15–30 min. The heating was carried out by Dr. D. A. Melford or by Mr. B. L. Mordike of this Laboratory, and I wish to thank these workers for their help.

Experiments with diamond powder gave the following results. Heating to 1,200° C. produced little change and only diamond could afterwards be detected by electron diffraction. Heating to 2,000° C. produced a complete transformation to graphite. For intermediate temperatures of about 1,600° C. both diamond and graphite could afterwards be detected, but electron diffraction patterns also showed spots which were not due to either diamond or graphite. These spots could be indexed for a cubic unit cell, $a = 12{\cdot}3$ A. It is thought that they are due to some sort of intermediate arrangement of carbon atoms, possibly a regular array of diamond-like and graphite-like regions. The existence of such an intermediate structure is of obvious importance to our understanding of the way in which the change occurs. Thus Nath[1] postulated that the puckered {111} planes of carbon atoms of the diamond lattice would become flattened at high temperatures giving the plane hexagonal networks characteristic of graphite: the lattice would also have to expand in a direction perpendicular to these planes to give crystals of graphite which should then be of the rhombohedral type. There is, however, no evidence from the diffraction patterns for an abnormally high percentage of rhombohedral graphite in graphitized diamond, and it is difficult to see how any but a hexagonal intermediate structure could occur in the process that Nath visualized. The occurrence of a cubic intermediate structure must mean that all four {111} planes of the diamond are equally favoured in change. A detailed description of the diffraction patterns which reveal the presence of this intermediate structure will be published elsewhere.

Examination of graphitized diamond powders by transmission electron microscopy using both bright and dark field techniques showed that the graphite forms as crystallites about 100 A. across. These crystallites are formed on or within the individual fragments of the diamond powder which appear to retain their coherence and shape even after the conversion to graphite is complete. The graphite crystallites do not vary significantly in size with temperature of graphitization over the range investigated (1,400–2,000° C.), but they are, of course, more numerous for the higher temperatures.

With large single crystals the sequence of changes described in Table 1 was observed visually after graphitization.

Table 1

Temperature of graphitization	Appearance
1,200° C.	Slight dulling of surface
1,400° C.	Definite grey colour
1,500° C.	Diamond appears dark grey but still translucent
1,800° C.	Diamond black, opaque and starting to break up
2,000° C.	Small black fragments

Fig. 6. Phase contrast optical micrograph of the feature of Fig. 3 after abrasion with alumina

These changes are similar to those described by previous workers[2,3]. Examination of the surfaces with an optical microscope showed no apparent change in the microstructure for graphitization at temperatures below 1,500° C. However, between 1,500° C. and the break up at about 1,800° C. marked changes in the surface topography did occur. Fourteen faces on eight diamonds graphitized at temperatures in this range have been examined. The features produced by the heat treatment on these faces were substantially similar, though at different stages of development. On three faces (two natural octahedral {111}, and one polished cube {100}), the features were particularly regular and well defined. These faces have been studied in detail, since they provide most information about the way in which graphitization occurs.

One of the natural octahedron faces is shown in Fig. 1: this had been graphitized at 1,800° C. The face is covered with dark patches which, though sometimes rather irregular in outline, do show a tendency to have a triangular shape. Examination at higher magnification revealed the presence of numerous similar but smaller triangular features. The surface relief was investigated using reflexion electron microscopy and it was shown that the triangles, etc., represent raised regions: the more regular of them are pyramidal in shape. The triangles are oriented with their sides parallel to the edges of the face, but they point in the opposite direction to the face. The polished cube face after graphitization at 1,800° C. showed similar features, but in this case they are square in outline and more regular in shape. An example is shown in Fig. 2. The features are again raised pyramids, and each has a central dark spot which represents a more sharply raised region. They have a wide variation in size, ranging from the limit of resolution of the optical microscope up to 0·3 mm. across for one particularly large composite feature (shown in Fig. 3). In each case where the height was measured it was found to be of the order of one tenth of the width of the feature. The squares are oriented, in some cases parallel to the crystallographic axes and in others at 45° to them. It can be seen that the large composite feature of Fig. 3 has three V-shaped limbs. These are portions of pyramids sloping upwards towards the irregular central region. Fig. 4 is a reflexion electron micrograph of one of these limbs (*X* of Fig. 3). The height of the point *A* above the general level of the surface is 4μ; the irregular central region is considerably higher.

The graphitized diamond on which the features shown in Figs. 2 to 4 appeared retained its original shape but became black and opaque after the heat treatment. It seemed likely that the graphite had formed as a surface layer (cf. Friedel and Ribaud[2]). To test whether or not this was so, the graphitized diamond was rubbed with a paste of water and fine alumina on a soft cloth. It was found that this treatment removed a surface film and that the underlying material was colourless and transparent—in fact, diamond. It was possible to estimate the thickness of the surface graphite layer in the following way. The abrasion with alumina removed the surface graphite layer in patches. The change in height at the edges of these patches was quite sharp, and it seemed that the abrasive had removed the surface layer by some sort of flaking process in which the entire thickness of the layer came away. A reflexion electron micrograph of a region at the edge of one of the patches is shown in Fig. 5. The thickness of the graphite layer could easily be measured from the length of the shadows cast by its edge. The abrasion grooves which were present on the original polished diamond surface before graphitization could also be seen after graphitization, both before and after the abrasion with alumina. Thus, the thickness of any layer removed from the top of the graphite layer by the abrasion with alumina was less than the depth of these grooves. For the film on the (100) surface which is being described, this was not more than 0·1μ. The remaining film, as seen in Fig. 5, was 0·5μ thick, and so the total original thickness of the graphite surface layer could be given as 0·6 ± 0·1μ.

The effect of the abrasion with alumina on the large feature of Fig. 3 is shown in Fig. 6. The rougher regions where the surface graphite layer has been removed can be seen by comparison of Figs. 3 and 6. Examination of the surface by optical microscopy using illumination from behind showed that these rougher regions were transparent and that the central feature was opaque and spread slightly sideways

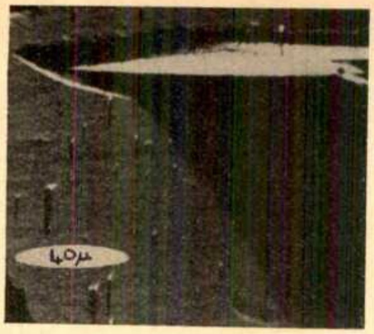

Fig. 7. Reflexion electron micrograph of the limb *Y* of Fig. 6

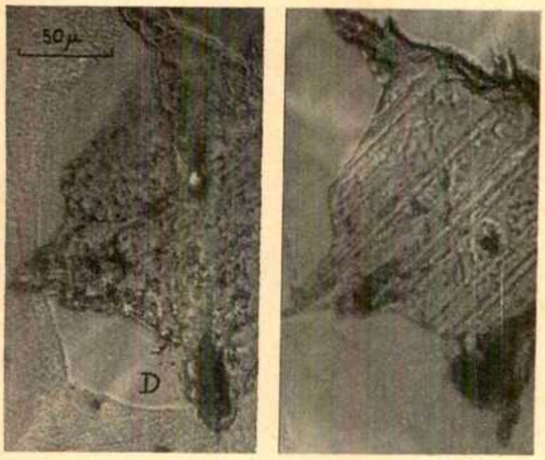
beneath the surface of the diamond. The V-shaped limbs were still present and could be seen to consist of transparent material. Reflexion electron microscopy (Fig. 7) and optical multiple-beam interferometry showed that they were still pyramidal in shape. The ridge of the limb *X* was found to have a slope of $2 \cdot 4° \pm 0 \cdot 1°$ and the point *A* to be $4 \cdot 2 \pm 0 \cdot 4\mu$ above the level of the original flat graphite surface (the level of the region *B* of Fig. 4). It follows that diamond has been transported to a position above the original level of the diamond surface. The only ways in which this can have happened are through plastic or elastic deformation of the diamond.

It does not seem to be possible to explain this transport of material in terms of elastic deformation of the diamond. The change in slope at the base of the pyramids is extremely sharp (Fig. 7), and it can easily be shown that the stresses necessary to produce so sudden a bending elastically would be impossibly big. One would, therefore, have to suppose that the stresses were relieved by cracking. This would have to be on such a scale that it should be readily visible. In fact, no evidence of such cracking could be observed even after the surface layers had been removed by polishing on an abrasive diamond wheel. Optical examination following this polishing did, however, give a confirmation of the nature of the feature. Fig. 8*a* was taken after the top of the feature had been polished away; the tops of the truncated pyramidal limbs (such as *D*) appear smooth and homogeneous in contrast to the rougher central region. Fig. 8*b* was taken after further polishing and represents a section of the feature a few microns below the original level of the surface: the region under the pyramidal limbs is indistinguishable from the surrounding diamond. It is concluded that the central region which is opaque and almost certainly graphite represents a nucleus of graphitization and that this, owing to the difference in densities, has expanded, forcing the surrounding diamond to deform plastically.



(*a*) (*b*)

Fig. 8. Phase-contrast optical micrographs of part of the feature of Fig. 6 after high-speed abrasion with diamond powder: (*a*) the top of the feature only has been removed; (*b*) abrasion has been continued and the surface seen here is a section through the feature a few microns below the original surface of the diamond

There is thus strong evidence which suggests that plastic deformation of diamond can occur at a sufficient temperature. This observation is of considerable interest since diamond is at normal temperatures a very brittle solid and all attempts to produce plastic deformation of it in the cold have met with at best doubtful success. There are, however, previous reports of plastic deformation being produced in this material at high temperature. Friedel and Ribaud[3] reported a relaxation of birefringence in a diamond heated to 1,880° C.: they interpreted this as indicating that plastic deformation had occurred. Evidence that plastic deformation can occur during the polishing of diamond was found by Seal and Menter[4]. Diamond is normally polished with diamond dust on a high-speed lap, and the conditions of abrasion are such that local frictional 'hot-spots' of 1,000° C. or more are almost certainly produced. Thus, high temperatures would again be involved in the plastic deformation. There is also evidence[5,6] that slip has occurred in some natural diamonds at some time during their geological history—very probably at high temperatures.

The particularly large feature which has been described was chosen for detailed study because of its size. The smaller features do, however, appear to be similar to it, and it is inferred that they are of the same nature. The experiments in which the surface layers of the diamond were polished away showed that these smaller features extend into the diamond to a depth comparable with their width in the surface. Thus, it is thought that all the raised square features seen on the {100} face and the triangular ones on the {111} faces represent nuclei of graphitization. These nuclei only occur near the surface of a diamond crystal and not within the bulk of the diamond.

The reason for this may perhaps be found from the following considerations. One may suppose that an incipient nucleus of graphite has formed within the bulk of a comparatively large mass of diamond. The nucleus originated in a smaller volume of diamond: it is therefore under compression from the surrounding diamond and occupies a smaller volume than it would otherwise have done. The diamond is in its turn under stress. The pressure within the nucleus can be calculated if simplifying assumptions are made. It is assumed that the nucleus is spherical, that it and the material surrounding it are both isotropic, and that the deformations are entirely elastic. The problem then becomes an elementary application of the laws of elasticity and the pressure is found to depend only on the compressibilities and densities of diamond and graphite and not on the radius of the nucleus. The numerical values of the compressibilities and densities at 1,800° C. are not known, but if the room-temperature values of these quantities are used then the pressure is found to be of the order of 10^5 atmospheres. Such a pressure would probably be sufficient to make diamond the thermodynamically stable form of carbon. Thus the nucleation of graphite will not occur within the bulk of the diamond since the pressure produced in an incipient nucleus will be sufficient to inhibit the transformation. There is experimental evidence that pressures of the order of 10^4 atmospheres are sufficient to inhibit the transformation of diamond to graphite even though diamond is still thermodynamically unstable[7].

These considerations no longer apply, of course, at the surface of the diamond, and graphitization would be expected to proceed inwards from the surface, as is in fact observed. Moreover, an incipient nucleus just below the surface (forming perhaps at a dislocation or other fault in the diamond) might expand suddenly and burst through the thin shell of diamond above it. This is thought to be the explanation of the raised features which have been described. They are, as it were, miniature volcanoes which have burst through the surface of the hot diamond and forced it to deform plastically.

I wish to thank Dr. F. P. Bowden for his interest and advice, and Industrial Distributors (1946), Ltd., for a grant to the Laboratory.

TYPHOON EFFECTS AT JALUIT ATOLL IN THE MARSHALL ISLANDS

By Dr. DAVID I. BLUMENSTOCK

Pacific Area Climatologist, U.S. Weather Bureau, Honolulu, Hawaii

ON January 7, 1958, a small, very intense typhoon passed directly over Jaluit Atoll in the Marshall Islands (5½° N., 169½° E.). The first reports thereafter indicated that the typhoon had wrought many profound changes, especially in its effects upon the morphology of several of the islets and upon the vegetation and soils. Accordingly, the Pacific Science Board of the U.S. National Academy of Sciences, acting together with the Office of Naval Research and the U.S. Trust Territory of the Pacific, sponsored the formation of a party of seven scientists to conduct a brief, but intensive, field study at Jaluit. In addition to myself, the field party included Dr. A. H. Banner, director of the Marine Biological Laboratory, University of Hawaii; Dr. F. R. Fosberg, Pacific Vegetation Project, U.S. Geological Survey; Dr. J. Linsley Gressitt, chairman, Entomology Department, Bishop Museum; Dr. Edwin D. McKee, geologist, U.S. Geological Survey; Dr. Herold J. Wiens, professor of geography, Yale University; and Mr. J. B. Mackenzie, who has been director of the Agricultural Experiment Station maintained at Jaluit by the U.S. Trust Territory of the Pacific during the past several years. It is the purpose of this article to report very briefly and in a preliminary sense on the principal findings of this field party, which studied conditions on several different islets of Jaluit during April 24–May 2.

The Typhoon

Because of the paucity of weather observations over the ocean to eastward, the storm that struck Jaluit was not known to be of typhoon intensity before it struck. It was, however, being carried as a storm that had appeared at Palmyra Island (5° 53′ N., 162° 5′ W.) and was approaching Jaluit from the east. After striking Jaluit, the storm moved on a west-north-west heading through the Marshall and Caroline Islands and into the Philippine Sea, where it died out. Among the islands seriously afflicted by the storm were Ponape, Truk, and the Hall Islands, all in the Caroline Islands. When the typhoon intensity of the storm was first established it was named 'Ophelia'; and that name will be used here.

At Jaluit, judging from eye-witness accounts and from the field evidence, 'Ophelia' produced winds with sustained speeds of at least 125 knots and brought ahead of it and with it pronounced storm tides on which large wind waves were superimposed. Strong winds came initially from the north-east quadrant, then backed through west to south. There was at least one distinct lull, indicating that the eye of the storm crossed the atoll. There was initially a series of wave surges from the east, and these inundated several of the islets along the eastern reef, in one instance to a depth of 6 ft. above the ground in a locality that is more than 8 ft. above mean sea level. These first inundations occurred between late morning and mid-afternoon (180th meridian time) and were quite promptly followed by much lesser inundations upon the islets along the western rim, the wave having been renewed within the lagoon, which is about 15 miles wide (from east to west) and 30 miles long (from north-north-west to south-south-east). Later, in the afternoon or early evening, there was further, but only partial, inundation from waves moving eastward in the lagoon and waves moving south-eastward over the ocean to the west of the atoll. By dawn on January 8 the storm had subsided and the wind had become easterly, the normal trade-wind direction.

Geomorphic Changes

The observations of McKee and Wiens in particular, but also those of the other members of the party, led to the identification of several new geomorphic features, especially on those islets that suffered major inundations. These include depositional and erosional forms.

The chief depositional forms produced by the storm were locally prominent gravel ridges upon the reef flat on the ocean side of some of the eastern islets; new or augmented beach ridges of gravel; gravel sheets, often tongue-shaped, extending across two-thirds of the islets in many places; and outwash features on the lagoon-side of the eastern islets. These lagoon-side sediments were strewn upon the reef and beyond into deeper water, as was shown by bottom samples obtained by Banner and McKee. They also may have helped form the gravel bars observed in some locations on the lagoon-side, both on the reef flat and beyond, though these bars also contain sediments derived from the floor of the open lagoon itself.

The most prominent erosion feature was the channels scoured out by the water. The best-developed ones originated at a break in the old beach ridge on the ocean-side of the eastern islets and extended several hundred yards across to the lagoon-side, where they gave rise to pronounced outwash features. Minor erosion features include plunge holes and scour pits.

Soils

On those eastern islets that were awash, the soils existing prior to the storm were either buried or scoured out over wide areas. On the islet of Mejatto, for example, more than half of the pre-existing soil now lies beneath a sheet of coral rubble that is from 5–6 in. to 2½ ft. thick. Severe scouring has sluiced off about one-fourth of the soil. The remaining 15–25 per cent is either partially eroded or else persists with little or no change, except, perhaps, in salinity.

A discovery made by McKee and Fosberg may prove to be of special interest. In a well cross-section, at a depth of about 3 ft., they found an undisturbed soil profile overlain by coral rubble to provide a disconformity that is precisely analogous to that produced by 'Ophelia'. This suggests that it might be possible to date, by the carbon-14 technique, those typhoons in past centuries that were sufficiently intense and sufficiently 'on target' to yield gravel sheets upon atolls anywhere.

Vegetation

The principal broad-scale effects of the storm upon the vegetation is well summed up by Fosberg in the introductory portion of his report (now in manuscript). His remarks should be viewed in the light of the fact that prior to the storm Jaluit was densely vegetated, since it lies in an area where the rainfall averages close to 200 in. a year.

"The effects of Typhoon 'Ophelia', even on the same vegetation type, or on the same plant, were by no means identical in all localities and parts of the atoll. In general, the islets on the eastside of the atoll suffered much more damage to their vegetation than those on north, south, and west. Also . . . narrow islets and parts of islets were far more affected than broad parts. This was well illustrated on Jaluit Islet, where the narrow parts south of Jabor were in places completely stripped of vegetation. . . .

"Many trees were uprooted. . . . Some were snapped off. Branches were broken or torn off of most of those that remained standing. Some exotic plants were killed or their above ground parts killed by salt. In places large scale burial of plants by gravel occurred. Elsewhere the soil with its vegetation was scoured away. Many tree trunks were seen in the lagoon on the shallower slopes along the east side. Masses of vegetable debris were strewn at random on the shallower slopes along the east side."

From the observations of Fosberg, Wiens and Blumenstock it is estimated that among those islets studied the greatest destruction was on Mejatto and northern Jaluit, both islets on the eastern reef, where 70–90 per cent of the trees were either completely uprooted or snapped off below the crown; while the least destruction was on western islets, where only 20–50 per cent were uprooted or snapped off. As for the comparative resistance of different tree species to the wind, Fosberg observes that *Pemphis*, *Cordia*, *Calophyllum*, *Casuarina* and *Bruguiera* "perhaps stood up best", while *Pandanus*, breadfruit and *Terminalia catappa* "perhaps fared worst".

Terrestrial Fauna

Gressitt observed that there was no evidence that the storm had eliminated any terrestrial faunal species. There were, however, pronounced effects upon populations and breeding-rates, with local extinction where vegetation was eliminated. He states: "Groups which seem to have suffered most appear to be rats, soil insects, grasshoppers, and scale insects. The birds (sea and shore birds, dove, cuckoo), lizards (geckos, skinks), brackish water shrimps, amphipods, land crabs, and spiders seem to have suffered very little. . . . *Culex* mosquitoes are breeding abundantly in cisterns which were inundated by sea water. House-flies and other filth flies are breeding abundantly, partly in privies as usual, and partly in some of the piles of accumulated decaying vegetation. Other insects found in the latter habitat, and under bark of dead trees, are breeding up large populations because of increase in their habitat as a result of the extensive killing and felling of trees and other plants. Still other insects, mainly moths and hemipterans, are breeding up large populations on new growth, apparently as a result of greater mortality among their parasites".

Submarine Features and Marine Life

Banner examined the submarine conditions within the lagoon by diving to depths of 30 ft. and more in many different places. He also examined depositional materials on newly formed bars and upon the islets, with special reference to its probable derivation. It was not possible, however, to observe the submarine features along the reef front in the surge channel zone because of heavy surf conditions.

On the bottom of the lagoon below low low-tide there was no evidence of disturbed conditions. Even delicate corals were not broken. In contrast, it seems likely that the outer reef front suffered pronounced changes, at least in some sections, because more than 75 per cent of the coral rubble forming the new ocean-side bar off Jaluit Islet is comprised of materials newly wrested from the outer reef.

The storm seems to have had no great effect upon the fish life in the lagoon. The inhabitants report better fishing since the storm than there was before; but it is possible that they gain this impression through having to fish more intensively than before, since vegetable food is in short supply.

Demography and Cultural Effects

Fourteen Marshallese died in the storm. Two more died of exhaustion immediately thereafter. This toll was surprisingly light considering the fact that there were some 1,200 inhabitants living on the atoll when the storm struck.

The low fatality-rate was the result of three factors. Imroj, the most densely populated islet, was not completely under water. Further, about 150 natives of Mejatto happened to be visiting Imroj for a social event when the storm waves swept their islet. And the natives on Jaluit Islet were able to take refuge in sturdy Japanese, cement-block buildings that were the only structures to withstand the storm.

On islets not under water, nearly all habitations were destroyed. Buildings made of board and corrugated iron blew apart. Native buildings, of grass, fibre and pandanus, blew down; but according to informants these were readily pushed back up, reinforced, and thus re-established after the storm.

Many of the inhabitants on the eastern, inundated islets have been forced to move to Imroj. Already, however, a few are beginning to move back home. Great quantities of supplementary food are being supplied by the U.S. Trust Territory Government, and these supplies will have to continue for a long time. Though replanting is taking place and though new vegetation is sprouting from vegetative debris, it will doubtless be at least a decade before the atoll has really recovered. Meanwhile, it is planned to re-study the atoll at intervals to learn how an atoll recovers from a typhoon strike.

FLUORINE COMPOUNDS

At the recent meeting of the British Association in Glasgow, one of the sessions in Section *B* (Chemistry), on September 2, was devoted to various aspects of the chemistry of fluorine compounds. Dr. J. Craik presided during the first part of the meeting, and Prof. R. A. Raphael for the latter part.

The first paper, given by Dr. J. C. Tatlow (University of Birmingham) was entitled "Fluorocarbons: a New Branch of Organic Chemistry". As a result of investigations during the past twenty-five years, it is now apparent that there exists a new type of organic chemistry, based upon the carbon–fluorine system, and paralleling the carbon–hydrogen system of ordinary organic chemistry. Thus, analogous to the saturated hydrocarbons, there are the fluorocarbons. Many open-chain and alicyclic compounds of this type are now known, with up to thirty or more carbon atoms. Fluorine can form the basis for this new branch of organic chemistry because the bond between a carbon and a fluorine atom is an extremely stable one, and also because the size of a fluorine atom is not too great to allow saturated fluorocarbon chains [$CF_3.(CF_2)_n.CF_3$] to exist without strain. If the atoms were very much larger, there would be insufficient room for enough of them to be carried on a carbon skeleton. However, fluorine atoms are bigger than hydrogens, and in a fluorocarbon they shield the backbone of carbon atoms, and thereby protect them from attack by chemical reagents, much more effectively than is the case with hydrogen substituents in hydrocarbons. Thus, two factors contribute to the great stability of fluorocarbons which are among the most unreactive organic compounds known. They are non-inflammable and are resistant to attack by acids, alkalis, oxidizing agents, and reducing agents.

As in orthodox organic chemistry, a vast range of compounds based on this parent series is capable of existence, since various other atoms and functional groups can be substituted in the molecules. Such derivatives are rarely prepared from fluorocarbons themselves (because of the great stability mentioned above they will seldom take part in controlled reactions). However, very many classes of fluorocarbon derivatives containing a variety of functional groups can be made in other ways. Simple examples of types now freely available are fluorocarbon carboxylic acids (for example $CF_3.CO_2H$), sulphonic acids (for example, $CF_3.SO_3H$), alcohols (for example, $CF_3.CH_2OH$), and amines (for example, $CF_3.CH_2NH_2$; compounds containing the groups $—CF_2.OH$ and $—CF_2.NH_2$ are not known). In all cases a complete homologous series can be made. The fluorocarbon part of the molecule can modify considerably the properties usually conferred on an organic compound by the functional group. Thus, the acids $CF_3.CO_2H$ and $CF_3.SO_3H$ are very much stronger than their analogues containing CH_3-groups. Usually, however, the fluorocarbon residue retains its inertness to chemical attack. Hydrogen and the other halogens can accompany fluorine as substituents on a carbon skeleton, and again various functional groups can be present as well, so that vast numbers of fluorine compounds are potentially capable of existence.

Recently, routes to perfluoro-aromatic compounds such as hexafluorobenzene have been opened up, and this most interesting new section of fluorocarbon chemistry is being investigated actively at present.

Because of their general stability, organic fluorine compounds are becoming increasingly important industrially as specialist materials. One typical example is in chromium plating, where long-chain fluorocarbon sulphonic acids (for example, $C_{10}F_{21}.SO_3H$), which are surface-active, can be employed to reduce spray above the plating baths. These use hot chromic acid, which attacks and destroys hydrocarbon-based detergents.

Fluoro-polymers are finding ever increasing applications. Recently, a series of rubbers has been introduced which are very stable towards heat and chemical reagents.

Mr. H. R. Leech (Research Department, I.C.I. General Chemicals Division) spoke next on "The Industrial Advance of Fluorine". A generation ago, fluorine was an 'awkward' element. The compounds in which it occurred naturally were inert and insoluble, but when they were brought into chemical usage, great difficulty was experienced in handling hydrogen fluoride and the element itself. This situation has now been changed completely, however. It is not always realized that fluorides are quite widespread in Nature, the element being thirteenth in order of abundance in the Earth's crust—more abundant than chlorine. Anhydrous hydrogen fluoride is now an important article of commerce and is made on a considerable scale from fluorspar and concentrated sulphuric acid. Handling it involves no great difficulties if the right equipment and techniques are used, and it may be transported in cylinders and tank cars. The same applies to fluorine itself.

One of the most important routes to organic fluorine compounds is by halogen exchange. The fluorine of hydrogen fluoride or a metallic fluoride is exchanged for another halogen in an organic structure. In this way, a range of simple fluoro-chloro-aliphatic compounds can be made. Compounds such as dichlorodifluoromethane have found wide application as refrigerants and as aerosol propellants. They are made in large quantities and are marketed under the trade names 'Freons', 'Arctons' and 'Isceons'. From compounds of this type, by simple reactions, the olefins tetrafluoroethylene and chlorotrifluoroethylene are obtained. These may be polymerized to give the fluoro-polymers, 'Teflon' or 'Fluon', and 'Kel-F', respectively. The first of these, particularly, has remarkable properties, being non-inflammable, and chemically stable. Also, it has valuable 'low friction' and 'non-stick' characteristics; one use arising from the last is for coating rollers which handle dough in bakeries. Polymers such as these are finding ever wider applications in many fields. Another valuable product of this halogen-exchange method of fluorination is the new non-inflammable anæsthetic 'Fluothane' ($CF_3.CHClBr$) recently made available by Imperial Chemical Industries.

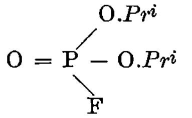
A second route to fluorine compounds is through the element itself. The preparation of fluorine by electrolysis of anhydrous hydrogen fluorine–potassium fluoride systems is now a routine operation and considerable quantities are used in the field of atomic energy. The preparations of chlorine trifluoride, sulphur hexafluoride, and uranium hexafluoride are carried out via elementary fluorine.

In the organic field, though much laboratory work has been done on fluorinations with the element itself, the reactions are difficult to apply on a larger scale and there has been little industrial development of this sort. The same is true of fluorinations involving high-valency transition metal fluorides such as cobaltic fluoride, though this is a valuable research method.

The electrochemical method of fluorination is potentially very useful, however. The organic compound to be fluorinated is dissolved in anhydrous hydrogen fluoride and electrolysed at voltages below those necessary for the liberation of free fluorine. Many functional groups are left intact in this process so that various types of fluorocarbon derivatives can be prepared in this way. Examples are fluorocarbon carboxylic acids, sulphonic acids, ethers and tertiary amines.

The development of the chemistry of fluorine is likely to see many further advances, and new kinds of compounds are constantly being made available and their potential value explored.

Dr. B. C. Saunders (University of Cambridge) presented a paper entitled "Physiological Properties of Toxic Organic Compounds containing Fluorine". He gave a most entertaining account, including some personal reminiscences of his own work. First, toxic fluorine compounds containing P—F linkages were described. Compounds of this type were first reported by Dr. Saunders and his colleagues in 1941. One of the most interesting was di-*iso*propylphosphorofluoridate:



$$O = P(O.Pr^i)_2F$$

and since then many similar compounds have been made. Tests carried out on the investigators themselves showed that exposure to low concentrations of the vapours of these compounds caused constriction of the pupil of the eye (myosis), powers of accommodation being affected and photophobia and intense headaches being experienced. Higher concentrations (tested on small animals) caused a quick knock-out action, the symptoms being muscular weakness, gasping, and finally cessation of respiration. The compounds are toxic by injection as well as by inhalation.

All these effects can be explained on the basis of interference with the enzyme cholinesterase, which is intimately concerned with the propagation of certain nerve impulses—hence the names nerve gases and anticholinesterases given to this class of compounds.

Dr. Saunders gave a brief account of the mammalian nervous system, and described how, when the acetylcholine liberated at the ends of the parasympathetic nerve fibres has performed its job by causing the appropriate physiological response, it is normally destroyed by being hydrolysed, by the enzyme cholinesterase, to choline and acetic acid. The nerve gas inhibits the action of cholinesterase and so allows acetylcholine to accumulate. This inhibition may be caused by the formation of a hydrogen bond between a hydrogen atom of the enzyme and a fluorine atom, followed by attachment of the phosphorus to a basic group of the enzyme.

These toxic compounds have found applications as 'systemic' insecticides which are absorbed by the plant and then transferred to other parts, so that any insects attacking the plant are killed. To be of use such compounds should be of negligible toxicity towards mammals and also should be broken down at such rates as to be entirely innocuous when the crops are harvested.

A second and most important group of toxic fluorine compounds is a series related to monofluoroacetic acid. Here, there is a C—F link, but with one such bond only in the molecule. These compounds are convulsant poisons. Comparable toxicities are shown by fluoroacetic acid, its salts, esters, and simple derivatives, whereas di- and tri-fluoroacetic acid and their derivatives are inactive. In general, most compounds that can be hydrolysed or oxidized in the animal body to fluoroacetic acid are toxic (fluoroethanol has properties identical with those of the acid). This applies also to derivatives of longer-chain ω-fluoroacids, $F(CH_2)_n.CO_2R$, where n is odd, though if n is even the compounds are non-toxic. It has long been thought that fatty acids are oxidized in the animal body by loss of two carbon atoms at a time, owing to oxidation at the carbon atom β to the original carboxyl group, and the toxic properties of the long-chain ω-fluorocarboxylic acids afford a striking proof of this theory. If the carbon skeleton of a toxic long-chain acid is modified so that β-oxidation cannot take place, the compound is devoid of toxic properties.

The reason for the toxicity of the compounds related to fluoroacetic acid is that they interfere in the Krebs tricarboxylic acid cycle. The body does not distinguish between acetic acid and its derivative with one fluorine substituent in place of a hydrogen, and fluoroacetate is built up into fluorocitric acid, causing a jamming of the normal tricarboxylic acid cycle.

The South African plant gifblaar contains sodium fluoroacetate and is extremely poisonous. It seems to grow best where the water has a high fluorine content. The enzymes involved in this synthesis of fluoroacetate are not yet known.

Dr. Saunders concluded by speculating as to whether other living systems, for example, green algae or even the animal body, by some 'deranged' mechanism might possibly synthesize organic fluorine compounds from inorganic fluorides. Some of these might be deleterious (for example, fluoroacetate), some beneficial (*cf.* recent reports of potent synthetic fluorine-containing analogues of steroid hormones).

The last paper, "Fluorine and Dental Decay, Fifty Years of Research", was by Dr. J. Campbell (Glasgow Dental Hospital). He emphasized that dental decay is the most prevalent human disease and is increasing at a rate which outstrips the capacity of the dental profession to deal with it. Some possible preventive measures, for example, reducing the consumption of sugar, are impossible to apply because of lack of public support. Fluoridation of domestic water supplies, however, will reduce dental caries by 60 per cent and has been recommended by the World Health Organization. Regarding the speculation raised by Dr. Saunders, Dr. Campbell pointed out that fluorine is in all of us, anyway, and is a normal constituent of human teeth. Many natural water supplies contain fluoride ion in relatively large quantities, much more than would be introduced by fluoridation.

Fifty years ago dentists noticed that children in certain districts of the Rocky Mountains had mottled teeth but were considerably less susceptible than other children to dental decay. They suspected a constituent of the water, and later, fluoride ion was identified as the responsible agent. Subsequent work showed that a fluoride ion content of about 1 p.p.m. would give a considerable degree of immunity to dental decay without discolouring the teeth. Such discolouring occurred only if the concentration was considerably higher. Various examples of the effects on dental health of high and low concentrations of fluoride ion in natural waters in North America and in Britain were quoted, including the cases of the children from North and South Shields. During the wartime evacuations it was found that the teeth of the children from South Shields were better than those of the children from North Shields and it was shown that the water supply in South Shields contains the optimum concentration of fluoride ion while that of North Shields is deficient. The advantages of artificial fluoridation of the water supplies of towns where the fluoride content is deficient are thus apparent. Intensive investigations have shown that artificially fluoridated water is identical with water that has been fluoridated by Nature, and that no industrial or other processes would be harmed by the addition of such small traces of fluoride ion. Water engineers are able to guarantee the accuracy and the uniformity of the additions of fluoride ion. Artificial fluoridation was first started thirteen years ago in certain towns in the United States and Canada, and has been completely successful. Dental decay has dropped by some 60 per cent and general health standards have been maintained. Fluoridation is now widely practised in North America (some 34 million people there are now receiving fluoridated water). It was started about two years ago in Britain on a very limited scale. All the results so far have been in accordance with expectation.

In conclusion, Prof. Raphael said that the issue of whether or not the fluoridation of water supplies should be carried out must be judged on the scientific facts which are now well established.

J. C. Tatlow

THE GEOLOGISTS' ASSOCIATION

A CENTENARY

By Prof. DAVID WILLIAMS
Imperial College of Science and Technology, London

Since its inception in 1858, when a few ardent amateur geologists met at No. 2 Upper Wellington Street, Strand, London, "modestly to seek mutual help as learners", the Geologists' Association has attracted recruits from all walks of life, from the veriest tyro to the savant steeped in geological lore, until now its membership is 2,032. The Association was opportunely born at a time when geology had so captured the imagination of the layman that the original prospectus could rightly claim that "There is no branch of Science which attracts so general—it may be said so popular—an interest as Geology". Only six weeks after the founding of an Association had first been mooted, nearly two hundred enthusiasts heard an inaugural address on "The Finding of True Facts".

Among the original objects and aims of the Association were the reading and discussion of papers, the exhibition of specimens, the dissemination of geological knowledge by printed *Proceedings*, and the holding of excursions. All these laudable aims have remained inviolate, though none has achieved such paramount importance as the excursions or field-meetings. Indeed, the longevity and continued prosperity of the Association is due in large measure to the genial companionship and mutual encouragement of its amateur and professional members, engendered and nurtured among hills and dales, mountain crags and lowland plains. Characteristically, to mark its centenary year, the Association held a series of field-meetings, ranging from Land's End to John o' Groats, besides which a wide range of geological guide books is being issued dealing with classic areas, the coasts of Britain and the environs of university cities in Britain.

By 1908, the jubilee year of the Association, the membership had risen to 661, by 1925 the total had reached 1,000, and in 1951 the 2,000 mark was passed for the first time. Candidates, irrespective of age or sex, have always been welcomed to membership, and many a novice has thus been inspired by the Association to become an eager disciple and exponent of geology. With few exceptions the present rules differ but slightly from those of a hundred years ago. The prospectus of 1858 stated that "the subscriptions have purposely, and with deliberate consideration, been fixed at a rate which will exclude none from the benefits it can give". Indeed, it is quite remarkable that not until 1952 was the Association compelled, by the fall in the value of money and the increased cost of publishing its *Proceedings*, to raise the annual subscription from 10*s*. to £1.

Unlike many other scientific societies, the Geologists' Association has never had a home or headquarters of its own; thanks to the kindness and generosity of various bodies and institutions, however, it has always been able to hold regular monthly meetings for the presentation of papers and the delivery of lectures. During the first few years these were held at St. Martin's Hall, Long Acre, at the College of Dentists and at the Medical Society of London; but from 1867 until 1939 the Association received spacious hospitality from University College, London, and since then it has enjoyed the privilege of meeting in the dignified rooms of its 'senior partner', the Geological Society of London.

In 1922, the Council sanctioned the formation of Local Groups, especially in areas where members were not within easy reach of ordinary meetings and field-meetings around London. The first to be formed was the North-East Lancashire Group in 1922; this was followed by the St Helen's District Group in 1929 (now defunct), the Midland Group in 1937, the North Staffordshire Group in 1949, and by the Jamaica Group in 1955. Incidentally, as part of the centennial celebrations, the Jamaica Group is erecting in the island, at Halse Hall, Kingston, a memorial plaque in honour of Sir Henry de la Beche, the first director of the Geological Survey of Great Britain, who lived there as a child and again in 1823–24.

In 1923, a Weald Research Committee was formed for the purpose of making a complete survey of the whole of the country involved in the anticlinal structure of the Weald; it has published a long series of original papers and reports of field-meetings, numbering almost a hundred in all. For several years during the 1920's, a Temporary Sections Committee organized the collection of records of transient sections, such as road excavations and building foundations, in the metropolitan area, a task which has been successfully continued by the London Naturalists' Society.

The Association is indebted to many of its members, both past and present, for generous bequests, some of which exist in the form of special funds or awards—as the Foulerton Award Fund, the Henry Stopes Memorial Fund, and the G. W. Young Investigation Fund.

Papers submitted for reading at ordinary meetings have steadily increased in number, while their diversity and standard arouse widespread commendation in geological circles. The first annual conversazione appears to have been held in 1863; during the long sojourn at University College the conversaziones attracted large gatherings to the main library and in later years to the Great Hall. Following a war-time interruption from 1939 to 1941 this popular function, thereafter named the annual reunion, has been held early in November at various institutions, usually at the Chelsea Polytechnic. During the present century the attendance has seldom been less than 50, and has sometimes reached 350.

One-day excursions, which started in 1860 on quite a small scale, have been a constant and enjoyable feature of the Association's activities. The first two-day field-meeting was conducted in 1863, and since 1871 outings of two days or more have been customary—apart from war years—at Easter and Whitsun. Moreover, during the summer months, long excursions. lasting up to a fortnight, have been arranged in various parts of the British Isles and on more than twenty occasions to Continental countries, including Austria, Belgium, Czechoslovakia, France, Italy, Norway and Switzerland.

One of the original aims of the Association was the printing of *Proceedings*, separate memoirs and notice papers. Until 1911 the *Proceedings* appeared every two years, but since then they have been issued as annual volumes in four parts, with maps and illustrations. Among the host of published papers, covering most facets of geology, a goodly proportion has dealt with the geomorphology and stratigraphy of southern England. Many of them rank as classical contributions to the literature of geology. The publication in 1910 of the jubilee volume, "Geology in the Field", describing areas in England and Wales visited by the Association, marked a milestone in its history. Apart from two months each summer, it has long been the practice to issue monthly circulars announcing forthcoming lectures and field-meetings.

The Association's century of progress has been largely due to the selfless devotion of its officers, and of the directors and secretaries of field-meetings at home and abroad, all of whom have willingly served without monetary recompense. Since 1900, the pleasant custom—never a rule—of electing presidents alternately from among amateur and professional members has been maintained with but one exception. The arduous office of treasurer and the key-post of general secretary have usually been in the competent hands of amateur members, while most of the editors have been professional geologists, and the less conspicuous but important roles of librarian and secretary to the Publications Committee have been filled by a line of enthusiasts, many of whom have served for long periods.

In the future, as in the past, amateurs will continue to be the mainstay of the Association; among their ranks there will always be some of international calibre, many will be active in the important task of assembling local details and recording ephemeral sections, and all will be attracted to the Association by a spirit of inquiry, by a stimulating out-door scientific pursuit with kindred souls, and by a love of Nature. Happy indeed is the Geologists' Association that it can look back with justifiable pride upon a hundred years of almost continuous expansion and progress, and forward in confident anticipation of still greater accomplishment.

Besides the launching of a series of guides, the centenary year is being commemorated by the publication of a volume entitled "The Geologists' Association 1858–1958", the delivery of several special lectures, the holding of a reunion on November 10 in the apartments of the Royal Society and the Geological Society, and a centenary year dinner on November 11 in the Connaught Rooms, London.

OBITUARIES

Prof. J. F. Joliot, For.Mem.R.S.

Le monde scientifique a été frappé par l'annonce de la mort de Jean Frédéric Joliot le 14 août à Paris.

Né le 19 mars 1900 à Paris, Frédéric Joliot a fait ses études d'ingénieur à l'École de Physique et de Chimie industrielles de Paris. Dans cette école il a pu profiter de l'enseignement de Paul Langevin, sur les conseils duquel il est entré en 1924 au Laboratoire Curie comme préparateur privé de Madame Pierre Curie.

Dans les premières années de son activité scientifique, Frédéric Joliot s'intéressait à la confection de minces écrans métalliques dans le but d'étudier leur conductibilité électrique. Depuis son mariage en 1926 avec Irène Curie, F. Joliot a commencé à s'intéresser aux problèmes de radioactivité et en 1930 il a soutenu sa thèse de doctorat ès sciences sur l'étude électro-chimique des radioéléments.

Esprit clair et méthodique il avait le don d'imaginer rapidement des expériences simples qu'il exécutait avec grande ingéniosité et habileté.

C'est entre 1932–34 qu'ensemble avec Irène Curie il a publié une suite de travaux remarquables qui dépassaient le cadre de la radioactivité proprement dite. En irradiant des cibles de glucinium par les particules α et en étudiant les radiations très pénétrantes signalées par Bothe et Becker en 1930, I. Curie et F. Joliot ont observé un nouveau phénomène très surprenant : un écran de paraffine placé dans le trajet de la radiation pénétrante devenait lui-même le siège d'une émission de protons de grand parcours, qu'ils expliquaient comme un effet photoélectrique de photons d'environ 50 MeV. sur les protons. L'observation de la projection des protons était importante pour la découverte du neutron, signalé peu de temps après par J. Chadwick sur la base d'expériences plus détaillées sur d'autres noyaux légers projetés dans différents écrans par le glucinium irradié par les particules α. Frédéric et Irène Joliot-Curie ont pu montrer à la suite le neutron était plus lourd que le proton.

Presque simultanément avec ces travaux I. Curie et F. Joliot ont fait des travaux importants sur l'annihilation du positon dans la rencontre avec un négaton et sur l'effet inverse, la création d'une paire négaton-positon dans la rencontre d'un photon γ pénétrant avec un noyau atomique lourd.

La découverte la plus remarquable de Frédéric et Irène Joliot fut celle de la radioactivité artificielle, couronnée par le prix Nobel de chimie en 1935. En irradiant des métaux légers, comme par exemple l'aluminium, par les rayons α, les époux Joliot ont observé que l'émission simultanée de neutrons et de positons cessait pour les neutrons, mais continuait à se produire pour les positons quand on enlevait la source α. L'intensité de l'émission des positons décroissait avec le temps comme le ferait une source radioactive naturelle. E. Fermi et ses collaborateurs ont pu bientôt étendre la radioactivité artificielle aux éléments émetteurs de négatons en bombardant des noyaux légers ou moyens avec des neutrons lents.

F. Joliot a fait des contributions expérimentales élégantes à l'étude de la fission de l'urane après capture d'un neutron. Avec Halban et Kowarski il a annoncé que la fission de l'urane est accompagnée de l'émission d'environ trois neutrons, ce qui a laissé entrevoir la possibilité d'une réaction en chaîne et la libération massive de l'énergie nucléaire. En 1940, Frédéric Joliot fait venir en Angleterre son important stock d'eau lourde provenant de Norvège.

Joliot est élu membre de l'Académie des Sciences de Paris en 1943. Pendant plus d'un an il est directeur du Centre National de la Recherche Scientifique, et il est nommé Haut-Commissaire au Commissariat à l'Énergie Atomique en 1945, dont il doit abandonner la direction en 1950 pour des raisons politiques. En 1956 il succède à Irène Joliot-Curie comme professeur à la Sorbonne et il devient directeur du Laboratoire Curie et des Laboratoires de Physique Nucléaire nouvellement installés à Orsay, près de Paris.

Pendant l'occupation Frédéric Joliot a milité dans la résistance ; pendant plusieurs années il a été président du Conseil Mondial pour la Paix.

Frédéric Joliot avait des manières simples et il était d'un abord facile. Quoique très tourmenté intérieurement, il avait une nature gaie et il se liait facilement d'amitié. Un deuil cruel frappe sa fille Hélène Langevin son fils Pierre et ses proches.

S. Rosenblum

Sir Douglas Mawson, O.B.E., F.R.S.

When towards the end of 1907 Ernest Shackleton passed through Australia on his way to the Southern Continent, the Australian Government gave him £5,000 towards the expenses of his venture, and in return he undertook to take Australian scientists with him. In doing so, they unwittingly turned the Pole-seeking quest of a gentleman adventurer into an expedition of major scientific importance. This same gift was also responsible for the introduction to polar exploration of the man who was destined to inspire and lead the first major Antarctic expedition in which adventure was subordinated to scientific inquiry. When *Nimrod* left Lyttelton, Douglas Mawson was a geologist already mature in experience and a lecturer in the University of Adelaide. In the next fourteen months he was destined to accompany his mentor, Edgeworth David, to the summit of Mt. Erebus through autumn frost and blizzard and to the South Magnetic Pole deep within the Antarctic plateau and back to the coast, a journey which involved well over a thousand miles of man-hauling of the severest kind.

Scott would have welcomed him on his final venture, but Mawson had finished with pole-seeking and had other fish to fry. In 1911 he left Australia with a well-found party sufficiently strong to man two bases the common objective of which was the scientific exploration and annexation of as much of the Antarctic coast south of Australia as could be covered in two years. With him he had the first air sledge and the first wireless installation ever to be established in Antarctica. In March 1913, this station, in spite of gales averaging 50 miles an hour for month on month—for he had chosen as his main headquarters the stormiest region of the whole landmass, where katabatic gales sweep downwards to the coast throughout the year—transmitted direct to Australia that first dramatic message recording Mawson's return from an ordeal I believe no other

man I have known could have survived. After losing one companion and practically all the party's food down a crevasse and seeing a second companion die of starvation and over-exertion by his side, he cut his tent down to half a tent, his sledge down to half a sledge and trudged into his headquarters after three further weeks man-hauling alone on just enough food to keep body and soul together.

It is a measure of Mawson's courage and determination that his second enforced year's stay saw the carrying through of scientific work as fine in quality as that of the preceding year when all was going well. A stream of memoirs that kept the Australian Government Press busy off and on for forty years is one fitting tribute to an enterprise brilliantly planned and executed in the face of exceptional difficulties.

In the years following 1913 Mawson did outstanding work as field geologist and teacher; but Antarctic science remained a major interest throughout a long life that came to an end on October 15. He went to Antarctica again in 1929 and 1930, when he discovered MacRobertson Land, Queen Elizabeth Land and the Mackenzie Sea, using a seaplane to increase his range of action. Since the Second World War he has been a driving force behind the Australian Antarctic organization, A.N.A.R.E. When Prince Philip visited Australia in *Britannia* in 1956, it was Mawson who took the chair at the Antarctic symposium that was one important feature of the Melbourne programme, and the paper he delivered showed that his interest was as strong as ever and his intellect as keen. In courage, determination, singleness of purpose, breadth of scientific interest and quality of mind, he was Australian man at his best and he will be sorely missed. No one will regret his passing on more than the few surviving companions of his early adventurous days.

RAYMOND PRIESTLEY

Prof. F. A. Paneth, F.R.S.

WORKERS throughout the world in many branches of science have learned with deep regret of the death in Vienna on September 17 of Dr. Friedrich Adolph Paneth, a director in the Max-Planck-Institut für Chemie in Mainz and emeritus professor of chemistry in the University of Durham.

Paneth was born in 1887 in Vienna, where his father was lecturer in physiology in the University. After studying science at the University of Vienna, he moved to Munich and, later, to Glasgow, where he worked for a year in the laboratory of Frederick Soddy. In 1912 he was appointed assistant at the Vienna Radium Institute, and six years later to a chair at the Prague Institute of Technology; during the ensuing fifteen years he held similar posts in the Universities of Hamburg, Berlin and Königsberg. The events of 1933 in Germany caused him to leave that country and to seek refuge in London, where accommodation was found for him at the Imperial College of Science and Technology; the welcome he received there was later put on a more formal basis by his appointment to a readership in atomic chemistry. In 1939, Paneth was appointed to the chair of chemistry at Durham, from which he retired in 1953 on reaching the age-limit. Even then he was not content to give up active scientific work, but returned to Germany to take up the post at Mainz which he held until his death.

Paneth's early education had been broadly based—to the end of his life he retained a keen interest in the humanities—and he was never in danger of too narrow a specialization in his work. His first major contribution, dating from his time at the Vienna Radium Institute, was made when he and Hevesy laid the foundations of the modern use of radioactive isotopes as tracers. At that time, of course, only lead and bismuth among the common elements were available in a usable radioactive form; but Hevesy and Paneth not only demonstrated that such materials could be used to follow the details of chemical reactions, but also went on to investigate in some detail the behaviour of trace quantities of such substances in precipitation, adsorption, electrochemical and colloid experiments.

After leaving Vienna, Paneth continued with this fundamental radiochemical work, but he was also led, by one of those almost accidental steps which not infrequently precede big developments in science, to the experiments which conclusively demonstrated the transitory existence of the simple aliphatic free radicals—perhaps his most important contribution to pure chemistry. He had been using the extreme sensitivity of the radioactive indicator technique to demonstrate the existence of the hydrides of lead and bismuth, and went on, with Hofeditz, to examine the pyrolysis of tetramethyl lead carried, in a stream of hydrogen, rapidly through a heated quartz tube. They demonstrated, in a classic series of experiments, that the immediate products of the pyrolysis are metallic lead and free methyl radicals, and established a procedure that has since found wide use in studies of free radicals. During this period he was also refining the technique of measurement of the very small quantities of helium formed—as α-particles—in radioactive decay processes. This work was continued after Paneth's arrival in Britain, and increasingly applied to the problem of 'age determination', especially of meteoritic materials. He began also to turn his attention to some chemical aspects of meteorology and, in collaboration especially with E. Glueckauf, much careful work was done on the concentrations of the minor constituents of the atmosphere.

On account of the Second World War, Paneth achieved little in Durham until 1945, when he returned from Montreal, where he had spent two years with the joint British–Canadian Atomic Energy Laboratory to which he had been seconded. He was determined to set up in Durham a research laboratory devoted to radiochemical studies and, with characteristic indifference to the administrative difficulties of the immediate post-war period, he achieved his aim: the Londonderry Laboratory for Radiochemistry was formally opened in June 1947. Here the work on the rare gases, which was now Paneth's main interest, was pressed forward, with especially intensive work on the problem of the ages of meteorites. The atmospheric work was also continued, in collaboration with the U.S. Air Force, which carried out experimental rocket firings to obtain samples of air from very great heights for analysis.

Paneth was keenly interested in the history and philosophy of science (and, indeed, in philosophy in wider contexts) and was often consulted about the naming of newly discovered elements, and other questions of chemical nomenclature. As president (from 1949 until 1955) of the Joint Commission on Radioactivity of the International Council of Scientific Unions, he provided a useful link between the physical and chemical approaches to problems of standardization in radioactivity. In 1926 he had been George Fisher Baker Lecturer at Cornell University, and his lectures formed the basis of his book, "Radioelements as Indicators"; with Hevesy he was the author also of "A Manual of Radioactivity", long regarded as a standard work on classical radioactivity. Paneth was elected to the Royal Society in 1947, and was honoured by many other learned societies, both in Britain and abroad.

It is clear that on his record as a scientist, Paneth is assured of a place in history, but something remains to be said of him as a person. He would not have counted himself a great experimentalist; rather his contribution was to create the conditions in which good work could be done—by selecting a happy team of collaborators, ensuring that they were not impeded by lack of equipment, and providing the necessary intellectual stimuli. He knew how to delegate responsibilities, and his colleagues knew that they could rely on his loyal support in anything they did on behalf of the Laboratory. Paneth was a natural linguist, and his command of English was extraordinarily good for one thrust into its use at so late a stage in his career. He was greatly in demand as a lecturer, and had a particular flair for exposition at the non-specialist level. These lectures were prepared with great care, and they were masterpieces of presentation, with just the correct blend of history, philosophy, wit, and hard scientific fact.

Paneth was a man of great personal charm—he can, for example, have had few peers in the matter of persuading museum curators to part with samples of meteorites—and he was blessed with a keen sense of humour. The numerous visitors to his Laboratory who enjoyed the hospitality provided at his home will long cherish memories of evenings of stimulating and amusing conversation. Their deepest sympathy will be extended to his widow, and to the son and daughter who survive him.

G. R. MARTIN

NEWS and VIEWS

Nobel Prize for Chemistry: Dr. F. Sanger, F.R.S.

DR. FREDERICK SANGER, who has been awarded the Nobel Prize for Chemistry for 1958, is a member of the staff of the Medical Research Council, and has spent the whole of his research life in the Department of Biochemistry, University of Cambridge, the University of which he was an undergraduate. The award has been made for his researches on the structure of the protein hormone insulin, the elucidation of which he completed in 1955, at the age of thirty-seven, after ten years of intensive research. The methods which he developed for this purpose are a model of effectiveness. When he began his investigations on insulin, Dr. Sanger first devised the use of dinitrofluorobenzene for the identification and estimation of the free amino-groups of proteins or peptides, and this method has since been widely adopted. By 1949 Sanger had shown that oxidation of insulin with performic acid, to break disulphite bonds, led to two separate fractions. Partial hydrolysis of the two separated portions with acid, and later with enzymes, yielded a series of peptides which he isolated by chromatography. The application of the dinitrofluorobenzene method to the peptides enabled Sanger and his colleagues to determine the sequence of amino-acids in the peptides, and so to deduce the sequences in the two large portions which had been formed by the oxidative fission of the insulin molecule. The results were such that a unique sequence of amino-acids could be ascribed to each of the two portions of the molecule. The determination of the position of the disulphide linkages involved the subjection of insulin to partial hydrolysis by enzymes under conditions in which the disulphide bonds remained stable. The cystine-containing peptides in the hydrolysate were separated and their structures determined by the methods he had previously developed. The structures of the cystine peptides which thus were elucidated showed that only one solution was possible to the problem of the distribution of the sulphide bonds in insulin. Two of these formed junctions between the two main peptide chains of the molecule, while a third disulphide link spanned four amino-acid residues in a manner similar to that previously deduced by du Vigneaud and his colleagues for the hormones oxytocin and vasopressin. Afterwards, Sanger and his colleagues showed that certain of the amino-acids within this intra-chain disulphide link differ in insulins from different species. Dr. Sanger's methods and example have stimulated much research in the investigation of protein structure, the limits of which have yet to be visualized, and they make clear the possibility that insulin may be completely synthesized in the laboratory, although this is unlikely to occur for some time to come.

Nobel Prize for Physics: Dr. P. A. Čerenkov, Dr. I. M. Frank and Dr. I. Tamm

THE award of the Nobel Prize for Physics for 1958 to the Russian physicists, P. A. Čerenkov, I. M. Frank and I. Tamm, for their work in the discovery and interpretation of the nature of Čerenkov radiation, is a fitting recognition of a scientific advance which has acquired great importance for experimental high-energy nuclear physics and cosmic rays. Čerenkov's contribution was to make, in 1934, a detailed study of the light emitted by liquids when they were exposed to radiations from radioactive substances. That certain substances were fluorescent under the influence of such radiations had been known since the days of Becquerel, but whereas fluorescent light depended markedly on the chemical nature of the substance, a weak residual light was found to be emitted even when all traces of fluorescent substances had been removed. This light was named the Čerenkov light; it was given a theoretical interpretation by Frank and Tamm in 1937. Frank and Tamm showed, on the basis of classical electromagnetic theory, that a charged particle travelling through a medium with a velocity greater than the velocity of light in that medium gives rise to an electromagnetic shock wave. This shock wave, which is analogous to the bow wave produced in water by a fast-moving ship, constitutes the Čerenkov radiation. Čerenkov light can only be observed in a medium which has a sufficiently high refractive index to bring the velocity of light in the medium below that of the charged particle; and it is emitted (like a bow-wave on water) at a definite angle to the direction of motion of the charged particle, the angle being a function of particle velocity. Modern Čerenkov counters make use of these properties to distinguish between particles of different velocities which emerge from the targets of the giant particle-accelerating machines.

Atomic Energy Patents: Mr. J. A. Gay

MR. J. A. GAY has been appointed patents exploitation officer to the United Kingdom Atomic Energy Authority in succession to Mr. T. Benson Gyles. Mr. Gay, who is thirty-six and graduated at University College, London, was formerly in the Commercial Department of the Authority's Industrial Group. In 1949 he was appointed development engineer to Standard Telephones and Cables, and in 1951 joined Messrs. O. W. Roskill, industrial consultants, as senior engineer. During 1953–56 he was with Isotope Developments, Ltd., and in 1956 joined the Authority's staff at Risley. Inventions developed in the course of atomic energy work and which are available for commercial exploitation continue to be filed at the rate of about eight a month. Many of them may be applied in a wide variety of industries, both inside and outside the atomic energy field, and the total number of inventions available for use by firms is now more than 400.

U.S. International Co-operation Administration: Visit to Africa

THE U.S. International Co-operation Administration is the organization through which the U.S. Government channels its funds for aid, of all kinds, to the different countries of the world. The Administration is the successor to the various agencies which have fulfilled this role since the days of the Marshall Plan and is closely associated with the U.S. State Department. For some months, the Administration has been exploring the possibilities of greater utilization of the scientific resources of the United States, and other countries, in attacking the problems of under-developed countries and territories, particularly in tropical Africa. The director of the Administration, Mr. James H. Smith, has started this week on a tour throughout tropical Africa, to examine on the ground the scientific work which is in progress. He is accompanied by Mr. Joseph C. Satterthwaite, recently appointed Assistant Secretary of State for African Affairs in the State Department, Dr. J. G. Harrar of the Rockefeller Foundation, Dr. Richard Bradfield, agronomist of Cornell University, and Dr. John M. Weir, who is working on tropical medicine for the Rockefeller Foundation. The Administration recently informed the Lord President's Office that Mr. Smith hoped to include two scientists from the United Kingdom in the party. In response to this invitation, arrangements have been made for Prof. G. B. Maegraith, professor of tropical medicine, University of Liverpool, and Mr. Dunstan Skilbeck, principal of Wye Agricultural College, to fly out this week to Africa and join Mr. Smith's party. The itinerary starts in Liberia and proceeds through Ghana, Nigeria, Kenya, Ethiopia, Sudan and Tunis.

Commonwealth Fellowships

THE new scheme for Commonwealth Fellowships, announced at the Montreal Conference in September, was warmly welcomed in both Houses of Parliament in the debate on the Queen's Speech on October 28 and 30. The scheme provides for 1,000 scholarships a year and Great Britain has announced her willingness to take half, while at the same meeting Australia announced that she was increasing her scholarships under the Colombo Plan by 150. There are now 38,000 Commonwealth and overseas students in Great Britain compared with 10,000 in 1951, and 10–12 per cent of all places in British technical colleges are occupied by overseas students, two-thirds of whom come from the Commonwealth: at the Imperial College of Science and Technology the percentage of overseas students is 38 and at the British Postgraduate Medical Centre, 60. Earl Jellicoe, in welcoming the scheme, referred to the crucial importance attached to education by all Commonwealth countries at Montreal and to the need for Britain to remain a great reservoir of humane wisdom and technical knowledge on which the Commonwealth and the free world could draw. Mr. P. Maitland particularly welcomed the assurance that these 1,000 scholarships for the interchange of Commonwealth advanced students would cover the humanities as well as science and technology; and Mr. J. Dugdale referred to the asset which such scholarships represented in Commonwealth relations and also to the value of an inter-Commonwealth service of technical experts.

National Science Foundation: Research for Teachers and Travelling Lectures

The U.S. National Science Foundation has invited universities, colleges, and other non-profit institutions with appropriate research facilities to submit proposals for support of Research Participation Programmes for Teacher Training. It is planned to support a limited number of experimental programmes which will provide research experience during the summer months for teachers of science and mathematics in high schools and small colleges, under the guidance of experienced scientific investigators. Courses combining laboratory experience with seminars on scientific subjects and research techniques will be provided with the objective of improving science teaching. Support will be provided by the Foundation for stipends and travel for approximately 700 teachers and for expendable supplies, secretarial and administrative expenses, and other institutional costs directly attributable to the teacher training aspects of the programmes.

The National Science Foundation is also to expand its programme of travelling science demonstration lectures, previously administered solely by the Oak Ridge Institute of Nuclear Studies, Tennessee, to include a few regional centres throughout the United States. Individuals will be selected by the regional centres to receive three summer months of intensive training designed to prepare teachers to give lecture-demonstrations in physics, chemistry, biology or mathematics in a number of high schools during the school year 1959–60. Emphasis is on fundamental scientific principles which can be demonstrated by simple equipment which teachers can construct. Each travelling lecturer will spend three to five days at 30–40 representative secondary schools throughout the area served by the regional centre, giving demonstrations using the special equipment which they carry with them, and assisting local science teachers.

Unesco Research Ship

A PROPOSAL that Unesco should sponsor an international research ship was strongly supported by a group of international marine scientists who have just concluded a series of meetings in Paris. The meeting was called to discuss Unesco's role in promoting international co-operation for oceanic exploration and was attended by consultants from scientific organizations in Australia, Denmark, Finland, France, the German Federal Republic, Italy, the Netherlands, Norway, Poland, Sweden, the United Kingdom, the United States and the U.S.S.R. The ship, it was pointed out, would supplement research already being carried out on a national basis by some of the larger countries and could also tackle oceanographic problems that cannot be undertaken by the existing ships. To meet this task, it was suggested that the ship should be of about 1,200–1,300 tons and some 220 ft. long. Laboratory space would be provided for six permanent scientists and additional accommodation for fifteen visiting experts and students in training. A supplementary proposal recommended that Unesco should operate a number of chartered research ships on an international basis. Emphasizing the importance of increasing the food resources of the world by development of the oceans' potentialities, the consultants also urged that Unesco and the United Nations Food and Agriculture Organization should direct the attention of all governments to the importance of marine research. Further specific aid was requested from Unesco in the form of research contracts for individual workers and laboratories, fellowships for training purposes, travel allowances for scientists participating in international co-operative projects, the assignment of experts to countries requiring technical assistance in this field and the provision of equipment and facilities for co-operative projects between countries. These proposals are being submitted to the Director-General of Unesco for further examination.

McGill University, Faculty of Engineering

The Faculty of Engineering of McGill University, in common with those of all other Canadian universities, is expecting a continuing growth in the number of applicants over the next decade, and is also anxious to encourage postgraduate studies to a greater extent than hitherto. The present buildings have been basically unchanged for some fifty years, although during that time, and particularly since 1945, relatively small additions have been made to accommodate the increased number of students admitted. In the session 1957–58 there was a total of some 1,800 undergraduate students in the Faculty, which represented the absolute maximum that the present buildings could take. In May 1958 ground was broken for a new engineering building to supplement the present facilities. This building, with an area of some 140,000 sq. ft., has been designed to provide lecture rooms and drafting rooms, particularly for the students in the earlier non-specialized years of the course ; to give, for the first time, proper quarters to the School of Architecture, and to provide completely new quarters for the Department of Electrical Engineering which was formerly housed in the old building. The release of this space from the old building will permit expansion of the Departments of Mechanical and Civil Engineering, where heavy installed equipment made it preferable to expand *in situ* rather than move into completely new quarters.

Mr. J. W. McConnell, the senior governor of the University, has made a magnificent gift which will cover the complete cost of this new building, which is expected to be opened in October 1959. The extra space then made available will make it possible for the faculty to embark upon a programme aimed primarily at the development of honours and graduate students in engineering, as well as permitting improvement in the quality of, and a small increase in the numbers admitted to, the ordinary engineering courses. The programme leading to the development of graduate work is already under way, and it is hoped soon to make appointments to three new chairs which have been created in control engineering, mining engineering and applied mechanics, and propulsion. It is also hoped that in the next few years a number of additional chairs will be created so that full use can be made of the new facilities.

Higher Education in the United Kingdom

The revised edition of the handbook for students from overseas issued by the British Council and the Association of Universities of the British Commonwealth under the title "Higher Education in the United Kingdom" (pp. 208. London: Longmans, Green and Co., Ltd., 1958. 5*s*.) contains much useful information. Thus it includes, besides a dictionary of subjects and facilities for study and the lists of addresses of universities, technical colleges and other institutions, which occupy the greater part of the handbook, tables of fees and notes on the cost of study and residence, and on life in a British university or technical college. There is a foreword by Dr. R. S. Aitken, and a short article on universities in the United Kingdom by Sir James Mountford and another on technical education by Dr. P. F. R. Venables. The handbook brings together much information of great value not merely to overseas readers but also to those in Britain who are concerned with advising and placing students.

British Commonwealth Collections of Micro-organisms

The United Kingdom National Committee of the British Commonwealth Collections of Micro-organisms is about to prepare a new edition of the "Directory of Collections and List of Species maintained in the United Kingdom and Crown Colonies". Directors of laboratories whose names appear in the 1951 edition will be asked to revise the information given in that directory, and to supply lists of micro-organisms now available for distribution. Other laboratories may have established general or specialized culture collections since the 1951 Directory was prepared, and if they are willing to make their cultures available to other interested workers they are asked to send lists before December 31 to Dr. S. T. Cowan, Secretary of the U.K. National Committee, at the National Collection of Type Cultures, Central Public Health Laboratory, Colindale Avenue, London, N.W.9.

Library Classification

A scholarly address, "Library Classification and the Field of Knowledge", delivered by Mr. D. J. Foskett at the annual general meeting of the North Western Group of the Reference and Special Libraries Section by the Library Association in Manchester, on February 26, has been issued by the Association as Occasional Paper No. 1 (pp. 15. London: Library Association, 1958. 2*s*. 6*d*.). Systems of classification, Mr. Foskett shows, arise not empirically merely as a practical convenience but as reflexions of the state of scientific and philosophical thought in any age, bringing together these parts of the field of knowledge that are seen to be clearly related. One must always be prepared to amend or overthrow existing systems which fall short of the requirements. Such discord as exists between the general classification systems and the requirements of modern research should not be allowed to continue.

Siemens Edison Swan Journal

THE format of the first number of the *Siemens Edison Swan Journal* (1, Summer 1958. Pp. 1–64. London: Siemens Edison Swan, Ltd., 1958) is remarkably good, as also the standard of the six articles which make up the contents. Tear-off abstracts in English, French and German complete with universal decimal classification numbers are provided. The *Journal* has been launched, the managing director, Dr. J. L. Aldington, says in his foreword, in order to provide additional opportunities for the staff to announce their achievements, and in one sense will supplement the technical press and journals of the learned societies, which from time to time include original contributions from the Company's staff, and in another sense will replace the old *Siemens Engineering Bulletin* by a more permanent and comprehensive record of the Company's contribution to electrical technology. The articles include a description of the "Centenary Neophone", a completely new telephone handset which the Company has recently produced, the main features of which are printed wiring, improved performance at lower cost, and reduction in size and weight; a review of recent applications in the light electrical engineering and cable industry; a brief discussion of some photoconductivity effects in grown crystals, particularly cadmium sulphide; and a survey of the manufacture of grids for radio valves.

Biochemical Pharmacology

THE first number has recently been published of a new international journal, *Biochemical Pharmacology* (1, No. 1; July 1958. Pp. 104. Subscription, including postage: (*A*) £6 (U.S.A. 17 dollars); (*B*) for subscribers certifying that the journal is for their own personal use, £5 5*s*. (15 dollars per annum). Four issues per volume. London: Pergamon Press, 1958). The journal will be devoted to "research into the development of biologically active substances and their mode of action at the biochemical and sub-cellular level". It will be under the guidance of an editorial advisory board containing many distinguished names from Europe and America. Papers will be in English, French or German. Short communications for quick publication will be accepted as well as full-length papers. It is intended to give emphasis to cancer chemotherapy and related studies, and this policy is reflected in the series of papers published in the first issue.

The Lichenologist

A NEW society, the British Lichen Society, founded early in 1958 to encourage the study and conservation of lichens, and conscious of the need to make up for past neglect of this interesting group of plants on the part of contemporary botanists, has now issued the first number of its journal, *The Lichenologist* (*Curator*, Dr. T. D. V. Swinscow, Everley, London Road, Knebworth, Herts.; *Hon. Secretary*, A. E. Wade, National Museum of Wales, Cardiff. Annual subscription and journal, 20*s*.). The major aims of the journal are to instruct and to communicate new information on taxonomic, distributional and ecological aspects. The first issue contains useful articles on the British species of *Cladonia* and *Collema*, notes on arctic–alpine and other lichens new to England, procedures for collecting and preserving lichens, and so on. This effort deserves the support of all who are interested in this group.

Foxboro-Yoxall's Training School

THE training school started in 1951 by Foxboro-Yoxall Ltd. at Wandsworth has now been moved to Redhill, Surrey. These premises have a greatly increased capacity, but in order to maintain an individual approach, courses are at present limited to nine students. The courses are of three weeks duration and comprise a maintenance course (*A*), designed to give instrument mechanics with limited experience in industrial instrumentation, practical training in the use and maintenance of Foxboro equipment; an advanced instrument course (*B*), designed for technical instrument engineers and covering the theory of control instrumentation and its application to industrial processes. Special courses related to particular user industries are also given from time to time. These have recently included one on instrumentation in the paper industry and another on instrumentation for coal-washing plants.

Leprosy Research Fund

THE Leprosy Research Fund was established in 1953, when Dr. R. G. Cochrane (of the Leprosy Research Unit, 11*a* Weymouth Street, London, W.1) was appointed technical adviser to the American Leprosy Missions, which had given financial aid to his researches on the histopathology of leprosy. The aim of the Fund is not to finance large research schemes, but to stimulate pilot research projects and inquiries. The Fund does not in any way compete with other organizations. It seeks, in fact, to help other organizations by indicating, through its pilot researches, problems that are sufficiently important to merit further consideration. The Fund also undertakes preliminary clinical trials of new drugs likely to be useful for the treatment of leprosy. For investigations of this kind only advanced lepromatous cases are taken, and the Fund is in touch with institutions all over the world. The Fund has studied the histopathology of leprosy for several years and has been able to supply workers with typical histological pictures of the various types and groups of leprosy. The Fund proposes to establish a unit containing a registry of clinical, photographic and histological records of the various types and groups of the disease, together with sets of slides, so that a world picture of the disease may be obtained for reference. It is estimated that the cost of such a unit will be about £2,300 a year.

National Museum of Wales

THE National Museum of Wales has recently issued a new edition of its "Illustrated Guide" (pp. 39 + 2 plates. Cardiff: National Museum of Wales, 1958. 1*s*. 6*d*.). It is, indeed, more than a new edition, for the subject-matter has been entirely re-cast and new illustrations have been included. The format is interesting and attractive and the typography clear and easy to read. Following a few notes on the building, well illustrated by clear plans, each department is dealt with in rotation but on a common plan. The purpose and policy of each is stated and brief allusion is then made to the chief exhibits. The "Illustrated Guide" is completed by an impressive list of publications and the whole is a model of what museum guides should endeavour to be.

Gibberellic Acid-like Substances in Higher Plants

As earlier studies have shown, gibberellic acid has notable growth-promoting effects when applied to dwarf varieties of *Pisum*, *Phaseolus* and maize, whereas tall varieties may be little affected. In an investigation of the distribution of substances similar to gibberellic acid in higher plants, M. Radley has demonstrated the presence of such substances in extracts made from seeds and from all parts of seedlings of tall and dwarf peas and from mature seeds of wheat and french beans (*Annals of Botany*, N.S., 22, 297 ; 1958). These substances were present in amounts equivalent to 0·1–0·3 μgm. gibberellic acid in 100 plants. It is stated that larger quantities were obtained from immature runner bean seeds, the substance being distributed between testas, cotyledons and embryos. A new biological test for gibberellic acid-like materials is described.

University News : Leeds

The following gifts have been received among others by the University of Leeds : £1,500 to the Department of Inorganic and Structural Chemistry from the Royal Society for scientific investigations on high-resolution nuclear magnetic resonance spectroscopy ; £700 to the Department of Botany from the Royal Society to purchase special equipment ; £1,000 to the Department of Civil Engineering from the Cement and Concrete Association towards the postgraduate course in concrete technology ; £2,715 to the Houldsworth School of Applied Science over three years from the Department of Scientific and Industrial Research for research on the brittle fracture of metals ; and £500 from the Shell Group of Oil Companies for postgraduate research in chemical engineering ; £700 a year for three years to the Department of Biochemistry from the Wellcome Trust for the salary and expenses of a research assistant.

The following have been appointed lecturers : Dr. P. B. Ayscough in the Department of Physical Chemistry ; Dr. R. G. Burwell in anatomy ; Dr. A. J. Kenny in biochemistry. The title of reader in textile physics be conferred upon Mr. H. J. Woods, senior lecturer in textile physics.

London

Mr. F. H. Ludlam, lecturer in the Department of Meteorology at Imperial College of Science and Technology, has been appointed to the readership in meteorology at the same College. The title of reader in aerodynamics in the University of London has been conferred on Mr. L. E. Fraenkel in respect of his post at the Imperial College of Science and Technology. The title of reader in biology in the University of London has been conferred on Dr. H. Kalmus in respect of his post at University College.

Sheffield

The title of emeritus professor of zoology has been conferred on Prof. L. E. S. Eastham, who retired recently (see *Nature*, 181, 1307 ; 1958). The following appointments have also been made : Mr. P. R. Becker, to be lecturer in the Electronic Computation Laboratory ; Dr. P. E. Brown, to be lecturer in geology.

Announcements

Mr. J. Tankard (British Rayon Research Association, Wythenshawe, Manchester) and Dr. F. O. Howitt (Wool Industries Research Association, Leeds) have been awarded Service Medals of the Textile Institute. The Service Medal was first awarded in 1940 and is given for valuable services rendered to the Textile Institute.

Starting with the January 1959 issue, Consultants Bureau, Inc., is undertaking the translation of all non-English articles appearing in each issue of the *Czechoslovak Journal of Physics* (annual subscription : 6 issues, 50.00 dollars). Further information can be obtained from Consultants Bureau, Inc., 227 West 17th Street, New York 11.

A symposium on "The Chemistry of Co-ordination Compounds", organized by the National Academy of Sciences, India, will be held in Allahabad on February 7 and 8. Further information can be obtained from Dr. Arun K. Dey, Department of Chemistry, University of Allahabad, India.

It is proposed to hold a symposium on "Cultural and Metabolic Aspects of Moulds", organized jointly by the Society for Applied Bacteriology and the Istituto di Sanita in Rome in the spring of 1960. The symposium will be open to *bona fide* workers in this field whether they are members of the Society or not. Those interested should write to Mr. G. Sykes, Boots Pure Drug Co., Ltd., Microbiology Division, Standard Department, West Bridgford, Nottingham, as soon as possible.

An international symposium on antibiotics will be held in Prague during May 17–23. The proceedings will be divided into three sections, dealing with problems of the biosynthesis of antibiotics ; the scientific pathophysiological basis of antibiotic therapy ; and the problems of fermentation technology and non-medical use of antibiotics. Further information can be obtained from the secretary of the symposium, Dr. M. Heřmanský, Antibiotics Research Institute, Roztoky, near Prague, Czechoslovakia.

A joint endocrine meeting will be held at the Royal Society of Medicine on April 24 and 25, 1959. It will be sponsored by the Section of Endocrinology of the Royal Society of Medicine and the Society for Endocrinology with the participation of the Society for the Study of Fertility, the Medical Section of the British Diabetic Association, the London Thyroid Club and the Endocrine Club, Glasgow. Short papers will be read and a dinner will be held on April 24. Further details can be obtained from the Honorary Secretary, Section of Endocrinology, Royal Society of Medicine, 1 Wimpole Street, London, W.1.

Erratum. In the communication entitled " 'Solubilization' of a Cytochrome *b* Component from *Micrococcus lysodeikticus*", by F. L. Jackson and Valerie D. Lawton in *Nature*, 182, 799 (1958), para. 3, line 7, for "529–530 mμ" read "429–430 mμ". This was overlooked in proof by the authors.

THE UNIVERSITY CHEMICAL LABORATORY, CAMBRIDGE

THE formal opening of the new University Chemical Laboratory in Cambridge by Princess Margaret on November 6 marks a deeply significant change in the topographic distribution of the University science laboratories. Hitherto, these had been compactly—in fact, all too compactly—built on each side of the Pembroke Street - Downing Street axis, physics, chemistry and zoology being on the north side of this axis, and geology, mineralogy and the other biological sciences on the south side of Downing Street. The Chemical Laboratory was originally built in 1887 at the corner of Pembroke Street and Free School Lane, but required several additions as the numbers of students increased : the two major additions occurred in the early 1920's, when the new organic wing was built with a considerable grant from the British oil companies, and when physical chemistry occupied the building in Free School Lane vacated by the Engineering Department. At the end of the Second World War, the Chemical Laboratory, by virtue of this piecemeal and improvised growth, had lost its original design and had become both inconvenient and uneconomic (in man-power and material) to run, was congested with students, and lacked space to house the modern equipment which it so badly required. The decision to migrate from the traditional science centre to the new site in Lensfield Road was based primarily on the virtual impossibility of rebuilding adequately on the old site, and also on the value of this site for the subsequent expansion of its cramped neighbours : the means for this migration were provided by a sympathetic Government Grants Committee, supported on the personal side very largely by the vigorous and steadfast appreciation of the position by Sir Alexander Todd.

The new laboratories consist essentially of two long rectangular blocks running parallel to Lensfield Road in an east–west direction, the block nearer to Lensfield Road accommodating the Department of Physical Chemistry and the other more distant and higher block accommodating the Department of Organic and Inorganic Chemistry. The two blocks are joined at the western end by a narrower block, which houses an additional part of physical chemistry, and also theoretical chemistry, spectroscopy, the library, administrative offices and canteens.

Between the two main blocks, on the ground floor, are two lecture-rooms each holding about 200 students, and a third lecture-room, to hold 450 people, is being added for both departmental and general University purposes.

At the east end of the organic–inorganic block an L-shaped extension is being constructed to provide extra research facilities and to accommodate the first- and second-year students in these branches of chemistry. When this extension becomes available, the migration of all chemical teaching and research from Pembroke Street to Lensfield Road will be complete, and the University of Cambridge will possess one of the most commodious and best-equipped laboratories for chemical teaching and research in the United Kingdom.

The main organic–inorganic block was constructed first and has now been in occupation for some time. The central portion consists of a basement which houses the store-room, workshops and (at the east end) the central heating station ; the ground floor is devoted to third-year organic teaching, the first and second floors to organic research, the third floor to inorganic and radiochemical research, and the fourth floor contains the plant room for the mechanical services, particularly those for the ventilation of the building and for the fans.

The central portion of the main physical chemistry block has a basement which contains the store-room, workshop and research accommodation, two floors devoted to teaching, a third floor to research, and a fourth floor which also houses a plant room.

The gross floor area of the complete building will be approximately 238,000 sq. ft.

The construction of the two major blocks embodies a number of novel features. In particular, the steel frame is built up of horizontal lattice girders, each about 45 ft. long × 3 ft. deep, welded together side by side to form a continuous frame on which each floor is constructed from pre-cast concrete slabs and a 3-in. concrete screed. These girders span the entire width of the blocks without internal columns, and thus allow the large teaching laboratories on the lower floors to be completely unobstructed, while on the research floors above considerable flexibility for subdivision is possible. The wall piers are of composite steel and concrete construction, the external walling being otherwise of 13½-in. solid brickwork faced with brown Buckinghamshire bricks.

The space within the lattice frame of each floor contains the horizontal runs of electrical and mechanical services. Hot-water heating pipes, which are attached to the underside of the frames, form, with removable aluminium panels, the heated Frenger ceilings.

The research floors have a central corridor, 6 ft. 9 in. wide, with rooms and laboratories on each side assembled on a modular basis, each module being fully serviced ; these research laboratories are separated by fireproof reinforced plaster panel partitions, which being non-structural are removable, so that the number of moduli forming any laboratory can be changed without undue trouble.

All laboratories are supplied with cold water at high and low pressure, with hot water (maximum temperature, 65° C.), distilled water, gas and compressed air (15 lb./sq. in.) ; certain laboratories are also provided with high-pressure air (100 lb./sq. in.), steam, reduced pressure (10 mm. mercury), and with oxygen. A water-softening unit, of capacity 400 gallons per hour, in the boiler house provides the water required for the steam generator, and for the automatic still which delivers distilled water into two 500-gallon polyethylene-lined storage tanks, whence it is fed through polyethylene pipes to all the individual laboratories. Polyethylene piping is also used to convey all cold effluent from the laboratory sinks, drip wastes, fume cupboards, etc., to the horizontal 4-in. bore cast-iron pipes which run through the

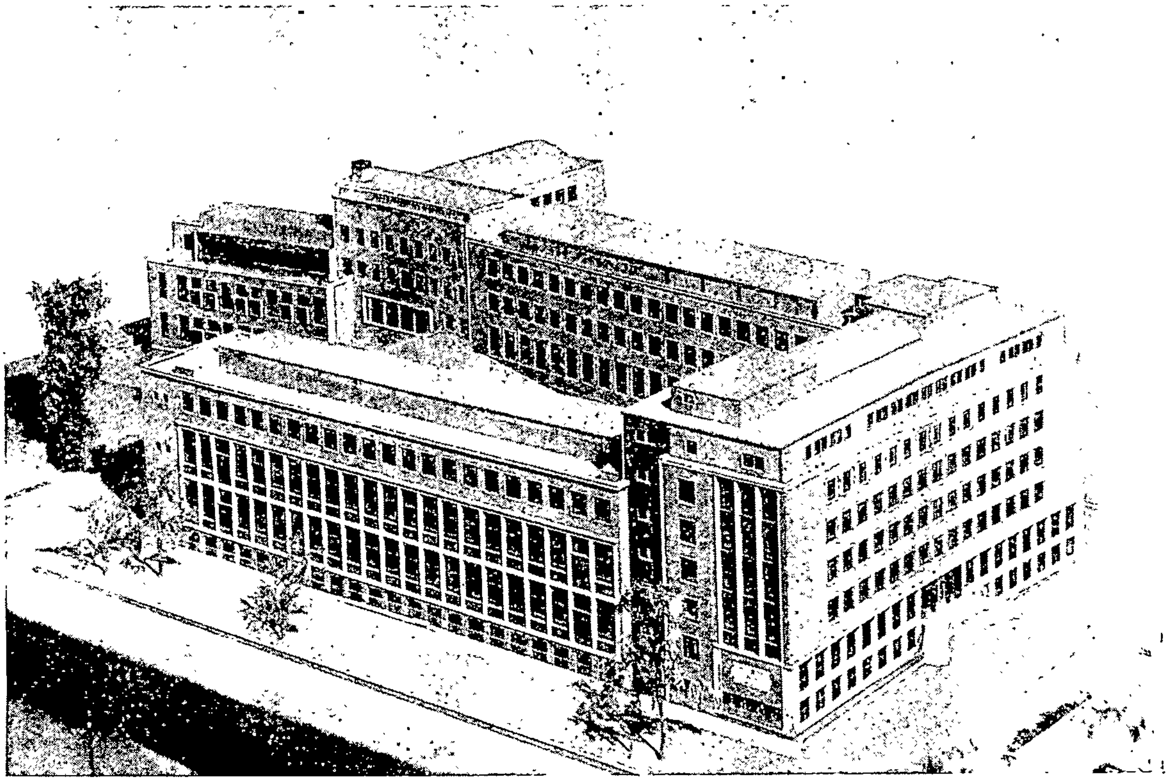


Fig. 1. University Chemical Laboratory, Cambridge. Photograph of the complete model of the Laboratory, viewed from the north-west. The main entrance is shown on the right. The long block in the foreground is occupied by the Department of Physical Chemistry, and that in the background by the Department of Organic and Inorganic Chemistry: the lecture rooms lie between these blocks. The two smaller blocks at the far left-hand corner are still under construction

lattice girders, and which are coated internally with acid-resisting plastic paint. Hot effluent from steam outlets is, however, carried through intermediate lead or stoneware piping.

To allow the desired flexibility in the size of the research laboratories, the teak bench tops are supported on cantilever brackets which fit into service racks designed to carry the tops at sitting or standing height, or to enable them to be completely removed. Independent cupboards of standard size but of various internal designs fit snugly beneath the bench tops: a research worker can thus choose a selection of cupboards suitable for his own work.

The design and construction of this Laboratory have presented many difficult and often novel problems. The University is particularly indebted to Mr. J. Murray Easton and Mr. S. E. T. Cusdin, of Messrs. Easton and Robertson, the architects, and to Mr. A. R. Gilson, the former superintendent of the Laboratory, who has closely and very effectively co-operated with them for the success of this project, which, in the hands of the contractors, Messrs. Kerridge and Co. (Cambridge), Ltd., and Messrs. Rattee and Kett, Ltd., has provided a chemical laboratory in which the University may well take great pride.

F. G. MANN

COSMIC RAYS

CONFERENCE AT DURHAM

A PHYSICAL Society Conference on "Cosmic Rays" was held in the Durham Colleges in the University of Durham on September 24 and 25. About one hundred delegates from most of the European centres of cosmic ray research gathered to discuss topics ranging from the cosmological significance of large extensive air showers to recent measurements of the cosmic ray intensity in deep Canadian mines.

The theme of the Conference was two-fold: the cosmic and geophysical significance of cosmic ray measurements, and the nuclear physics of single-particle interactions. The Conference was divided into short sessions in which an invited review paper of 45 min. was followed by a number of 10-min. papers.

The first session was devoted to a discussion of interactions in the energy-range 1–100 GeV. Recent results with machines were considered at the lower end of the energy region and the results of cosmic ray proton experiments for the remainder. Experimentally, several features appear to be clear: the inelasticity of proton interactions with light elements does not vary greatly with proton energy; the value is about 60 per cent, and the rate of production of heavy mesons increases slowly with increasing energy. Also clear is the inadequacy of the various theories of meson production—Fermi, Landau, etc.—to account for the observed angular distribution of meson production in the centre of mass system. The experimental results would be consistent with the isotropic emission of mesons from two centres moving away from the collision more slowly than do the original nucleons, but there does not seem to be any theoretical justification for this model. Since it is unlikely that machines capable of accelerating protons to energies much above 20 GeV. will be constructed in the next few years, attention is naturally focused on the cosmic ray experiments in this energy region. At present the interpretation of the experiments is difficult: the momenta of the primary protons are not measured, in fact, often the directions are not determined, and the secondary momenta are too high for accurate measurements. This point was well brought out in the first contribution, which described the results of a design study for an experiment in which accurate measurements of the parameters of the interaction would be possible. Such an experiment would be expensive by cosmic ray standards but not by machine standards ; it is perhaps within the scope of a collaborate university venture.

In the second session the energy-range was extended to 100,000 GeV. Most of the information in this region has come from studies of the so-called 'jets' observed in nuclear emulsions exposed in high-flying aircraft and balloons. The number of particles produced in the cascade resulting from some of the very energetic nuclear encounters (above a few thousand GeV.) is so great that the events can be seen in the processed emulsion with the naked eye. At these high energies there is quite copious production of particles heavier than the pion, for example, the ratio of the charged heavy particles to all charged particles is 18 ± 5 per cent. Another important result is that the interaction length of the secondaries of mean energy around 200 GeV. is very close to that found for pions and protons in the region of a few GeV. This result has important implications in the study of the development of the various components of the cosmic radiation through the atmosphere. Thus, for example, the pion flux is subject to the competing mechanisms of decay and interaction and is consequently sensitive to the value of the interaction length.

The energy-range under review was extended still further in the next session when various aspects of extensive air showers were discussed. The cosmological aspect is of supreme interest, bearing as it does on the origin of the cosmic radiation. The situation here has not changed over the past few years: the search for anisotropies in the primary cosmic radiation at energies up to 10^{18} eV. or so has still failed to produce statistically significant results. The need at present is for an order of magnitude increase in the size of the detecting arrays for extensive shower studies, and at least two such projects are afoot at the present time. Even with improved experimentation, however, the interpretation of the sea-level shower data is not straightforward. The electron component, which is traditionally measured, is subject to considerable fluctuations, arising in the main from the fluctuation in the height of the first primary proton interaction. For this reason attention is now being turned to the muon component for which the fluctuations are smaller, although difficulty is encountered due to the particle densities being considerably lower, at least for distances less than a few hundred metres from the shower core. The session finished with the description of a number of new techniques by which detectors of the necessary large area could be constructed.

The current interest in the International Geophysical Year was reflected by a session on cosmic rays and solar–terrestrial relations. A considerable mass of data is accumulating on this subject from measurements or the variation with time of the various components, particularly the neutron component. The spectacular increases in intensity during the big solar flares has emphasized the part played by the Sun in producing low-energy cosmic rays. There is as yet no completely satisfactory explanation of the way in which these particles are accelerated or of the modulation of the primary cosmic rays by the Sun's magnetic field, but the result of the analysis of the very detailed International Geophysical Year results may lead to a considerable advance.

The interaction of the primary cosmic rays with the Earth's magnetic field was discussed by speakers from the Imperial College of Science and Technology. Experiments over the past few years have shown that the position of the cosmic ray equator, that is, the locus of the minimum of the cosmic ray intensity, is not consistent with the magnetic equator based on an eccentric dipole field. The disagreement amounts to a westward displacement in longitude of about 45°, and an attractive explanation was the bending of the lines of force from the rotating Earth by a surrounding region of highly ionized interplanetary matter. The Imperial College group has shown, however, that the dipole approximation is not a good one even at the distance from the Earth where most of the magnetic deflexion of the primary cosmic ray takes place. A more accurate treatment of the effect of the Earth's field taking into account the various magnetic anomalies removes the discrepancy between the respective equators.

The development of the muon component through the atmosphere and below ground occupied the next session. It was demonstrated that measurements on the sea-level muon flux give information on the multiplicity and mass spectrum of the products of primary interactions. Comparison with the underground depth–intensity relation gives information on the energy losses of muons of energy up to 1,000 GeV.—information that is not available from other measurements.

With the introduction of new techniques of measurement, in particular the neon flash-tube of Conversi, and the consequent ease of measurement of high particle momenta, there has been something of a revival of muon spectrum measurements. Large magnetic spectrographs have been completed recently at sea-level at Cornell and Durham, and a number of smaller instruments are under construction for measurements of muon spectra in inclined directions and at various depths underground. The next few years should see significant advances in this subject.

The interactions of individual fast muons with nuclei were also discussed in this session. This interaction is via the flux of virtual photons accompanying the muon, and recent advances have been made both in the theoretical study and the experimental determination of cross-sections and other parameters of the interactions. Although there is still some slight doubt as to the way in which the original Williams–Weizsäcker treatment of the virtual photon flux is to be modified for ultra high-energy muons, the main features, such as the angular deflexions of the interacting muons and the multiplicity of the pion secondaries, are understood. The importance of these measurements lies in the fact that what is being studied is effectively the interaction of photons of energies much above those available from artificial sources. The most that can be said about the variation of photo-nuclear cross-section with energy at the moment is that there is no strong evidence to suggest a cross-section varying very much from 10^{-28} cm.^{2}/nucleon between 1 and 40 GeV.

The last session was devoted to a discussion of the results of recent experiments on low-energy muons and electrons. The general impression that emerges from studies of muon decay and capture is that whereas the decay process is fairly well understood there are still some uncertainties in the explanation of the observed capture-rates. The discussion of electron interactions centred mainly around the Stanford work on nuclear sizes. One of the most interesting results of this work is the small size of the electrostatic charge core of the neutron. The interpretation of this result is not clear and the confirmation or otherwise of this result by more accurate experiments is awaited.

The conclusions to be drawn from this rather overworked Conference appear to be that there is still much to be learned about virtually every aspect of the subject. It would appear that for some time to come cosmic ray experiments are likely to be the only source of knowledge on nuclear processes at energies greater than 20 GeV. A. W. Wolfendale

COMMONWEALTH UNIVERSITIES' CONGRESS, 1958

THE Eighth Quinquennial Congress of the Universities of the Commonwealth, the first to be held outside the United Kingdom, was held in Montreal during the first five days of September. The Congress had been preceded by a smaller conference of executive heads of the Commonwealth Universities, held in the University of Toronto during the previous week. At that conference, some useful exchanges of view took place on some current university problems. The Montreal Congress was attended by more than 400 delegates and guests, many of them accompanied by their wives. Among the guests were some twenty-four American university presidents and the members of the administrative board of the International Association of Universities. The Congress was probably the most comprehensive gathering of representatives of the university world of the British Commonwealth and the United States which has yet taken place. There was consensus of opinion that never before had so much mutual understanding been achieved, both by the sessions of the Congress and otherwise, of the general and detailed patterns of university institutions in the countries represented at the Congress. Most of the Congress sessions were held at McGill University, although one session was held in the University of Montreal. Both universities provided accommodation and lavish hospitality for the delegates and their wives.

At the opening ceremony on September 1, the delegates and guests were welcomed by Dr. Andrew Stewart, president of the University of Alberta, in his dual capacities of chairman of the Association of Universities of the British Commonwealth and president of the National Conference of Canadian Universities. The Congress was formally opened by the Right Hon. Vincent Massey, governor-general of Canada, who warned that universities to-day tread a dangerous path in increasingly accepting government money, offered because they are doing things that government wants done. "The intellectual duty of the university to remain free is," he insisted, "greater now than ever, and more difficult than ever before." The opening address of the Congress, on "Expanding Education", was then delivered by Sir Hector Hetherington, principal of the University of Glasgow, who described himself as the veteran who had attended all but one of the previous seven congresses. He referred to two new elements in the expansion of university education in all the countries represented at the Congress—that the required rate of expansion is abnormally high, and that what is wanted is not a general all-round expansion but one designed to take effect mainly in one direction, science and applied science. Sir Hector posed no new problems and proffered no new solutions. He explained how the present situation had come about and what steps had been taken, and were being taken, to deal with it. He propounded the principles which, in his view, needed to be kept in mind in the expansion of professional education, if it were not to become mere vocational training, and he urged the value of keeping the humanities, together with science, at the centre of the university stage.

The first ordinary session of the Congress, on September 2, was devoted to a discussion of "Who should govern University Policy ?" In this and subsequent sessions the speakers tended to outline the procedures and philosophies applicable to their own countries, and this brought to light rather unexpected degrees of divergence but there was very little attempt at synthesis ; and the Congress formulated no general conclusions. The first speaker, Dr. V. C. Fowke (Saskatchewan), was concerned primarily with internal controls over university policy, and dealt specifically with the Canadian universities. He directed attention to two diametrically opposed concepts of university government : one, that a university ought to be a self-governing community of scholars, and the other, that it is a business enterprise which is best governed by typically corporation methods. The written constitutions of the Canadian universities tend strongly towards the latter. The allocation of funds, the determination of priorities and the selection of personnel are all the responsibilities of lay boards which have no academic representation. Usage, however, makes wide concessions to self-government and it is the academic staff who determine whom they shall teach and how they shall teach, with control of examinations. They cannot have these controls without an effective voice in financial allocations. Chancellor L. A. Kimpton (Chicago), the second opening speaker, elected to defend the American practice of giving the university administrator more power, perhaps more dignity, than is usually accorded him in the British tradition. He pointed out that most lay boards in the American universities have only fiscal interest and power, and he claimed that the administrator should have an important role in determining policy because of the inherent limitations of the faculty. The defence of academic freedom is a matter to be undertaken by the university president, whose task will be the education of the public. Other functions of the president, in Dr. Kimpton's view, are: (*a*) the protection of the academic community from pressures which might make the university unbalanced; (*b*) to take strong remedial action with an inefficient or incompetent department, and (*c*) the raising of funds. None of these functions can be exercised effectively by academic bodies. In the ensuing discussion, Dr. T. Alty (Rhodes University, South Africa), doubted whether the principal or vice-chancellor of a Commonwealth university had functions very different from those of the American university president. He is a key figure and must exercise an important influence on university policy. Interpretation of the university to the public is not a function of the academic staff, and is best done by members of a lay governing body. But the determination of policy should be a co-operative enterprise; academic bodies, lay boards and university president all taking a share. Sir Keith Murray (University Grants Committee), while believing in self-government, stressed the need for lay participation, in which he saw four major advantages. The lay members can bring to the university the advantages of 'corporation' methods, they can exercise a semi-judicial function and help to solve otherwise insoluble problems, they can lighten the administrative load of the academic members, and they can help to promote public confidence, especially important as universities become increasingly dependent on public funds. Other contributions were made by Sir Charles Morris (Leeds), who agreed about the value of the lay members, but thought that the modern university should give the head of an academic department an important share in policy-making; by Prof. N. K. Sidhanta (Calcutta), who directed attention to the special problems of the 35 Indian universities, with some 800,000 students, of whom more than 700,000 were taught in the numerous affiliated colleges; and by Mr. A. Hakim (East Pakistan), Prof. K. E. Bullen (Sydney), Dr. C. H. Rautenbach (Pretoria), Prof. D. V. Cowen (Cape Town), President Grayson Kirk (Columbia), Mr. W. H. Gillespie (Canterbury Agricultural College), and Dr. H. B. Thom (Stellenbosch), who discussed the respective functions of the principal, the academic staff and the lay members in the determination of policy. There was a general appreciation of the valuable role of the lay member.

At the second session of the Congress Prof. J. F. Baker (Cambridge) opened a discussion on "Engineering Education, and its Place in the University". He gave a general survey of the engineering tripos course at Cambridge, an unspecialized course covering all the main branches of engineering science conducted in a single department of engineering. His satisfaction with the arrangements was not shared by President G. P. Harnwell (Pennsylvania) in respect of engineering education in the United States. Engineering was a latecomer among the academic disciplines; the lack of differentiation between professionalism and technicianism had operated to its disadvantage, and had hindered its recognition. Moreover, the greater emoluments and prestige of the practising engineer had adversely affected recruitment of academic staff. He thought that the closest possible association of engineering education with the universities should be maintained, and was unimpressed by the Soviet system of professional education in specialized institutes. President L. A. DuBridge (California Institute of Technology) asked where el

had responded rapidly to the indigenous educational demands of fast-growing frontier societies and populations. "Universities are at once the catalysts and creations of a changing society." Several speakers agreed with Dr. Logan about the need in present circumstances to establish new universities. An impressive account of the principles adopted in the institution and development of seven new university institutions in the British Colonies was given by Dr. W. Adams (Rhodesia and Nyasaland). Lord Sinclair (Bristol) thought that the ultimate success of the Rhodesian experiment was of great importance to the whole British Commonwealth. Dr. C. H. Wilson (Leicester) stressed that two conditions were needed to warrant the foundation of new universities —local initiative and support, and a demand from prospective students. Dr. R. B. Madgwick (New England, N.S.W.) emphasized the weaknesses of a system of tutelage by existing universities. Dr. T. M. Advani (Bombay) referred to the remarkable demand for education in India after independence. The desire for knowledge is great, but the desire for acquiring degrees even greater. In referring to the service which universities provide for the community the Hon. P. M. Sherlock (West Indies) pointed out that the university may become a powerful competitor for limited resources. Dr. N. A. Mackenzie (British Columbia) asked whether, when it is difficult to obtain staff of adequate quality for existing institutions, it is wise to found new ones, and Dr. V. K. R. V. Rao (Delhi), after pleading for a national organization to lay down the principles on which a new institution should be established, asked: "What is a university ?" At this stage these questions proved too difficult, and the Congress disbanded.

After the Congress, executive heads of Commonwealth universities and their wives paid a week-end visit to Washington and Philadelphia as guests of the Association of American Universities. In Washington they had the honour of being received by President Eisenhower at the White House, and of being addressed by Mr. Justice Frankfurter in the Supreme Court. The other delegates were entertained by Laval University in Quebec City. After the week-end, most of the delegates set off on one or other of eleven tours for which the transport costs were provided by a generous grant from the Carnegie Corporation of New York. Members of each party were thus enabled to visit some four or five universities in Canada and the United States, hospitality being provided by the universities concerned. For many of the delegates this was the most stimulating and rewarding part of their mission, as it allowed more intimate personal contacts than had been possible at the large Congress and gave a revealing insight into the workings of a variety of university institutions in the New World.

J. W. COOK

THE WORLD LAND USE SURVEY

THE World Land Use Survey owes its inspiration very largely to Prof. L. Dudley Stamp and his great achievement in carrying through in pre-war days the work and organization of the Land Utilisation Survey of Britain. A Commission, appointed at the International Geographical Congress held at Lisbon in 1949, was very impressed by the urgency of the problems of world population and world food supply and considered that "present factual knowledge is inadequate to serve as a proper foundation for schemes of improvement and development, especially in those areas which are commonly regarded as 'underdeveloped' ". It proposed, therefore, a World Land Use Survey that would record the present use of land in all parts of the world on a uniform system of classification and notation, basing the maps on field-work together with the interpretation of other material such as air photographs. It hoped that a series of maps on the scale of 1 : 1,000,000 might be published together with explanatory memoirs that would help in the understanding of the maps.

The work in different parts of the world has met with varying success. Some pilot surveys suggested that, elaborate though the land-use classification was, it often required further amplification, and sometimes modification. Aspects of the work have been taken up by Government departments, such as the Directorate of Overseas Surveys which has developed most usefully the interpretation of air photographs as a source of land-use data.

Some preliminary results are becoming available through the issuing of maps and reports. A map of Cyprus at a scale of 1 : 250,000 was published in 1956[1]. It was based on the stereoscopic examination of 10,000 photographs and was prepared in the Department of Geography at the London School of Economics under the direction of R. R. Rawson and K. R. Sealy. The first of the Survey's 'Occasional Papers', "Land Use Studies in the Transvaal Lowland", by Dr. Monica M. Cole, of the University College of North Staffordshire and formerly of the University of the Witwatersrand, also appeared in 1956[2]. It was a "contribution to the study of the opportunities and difficulties inherent in the savannah environment" and laid emphasis upon the many environmental factors that challenged the area's agricultural development.

Recently, the Survey has published the first of its Regional Monographs, "A Survey of Land Use in Hong Kong and the New Territories", by Dr. Thomas R. Tregear, lecturer in geography in the University of Hong Kong[3]. The volume includes a coloured land-use map at a scale of 1 : 80,000 distinguishing eight types of land use: woodland, scrub, rough grassland, 'badlands' that are heavily eroded, arable, swamp, houses with gardens, and built-up areas, including camps, cemeteries and other land that is agriculturally unproductive. Hong Kong illustrates in a special way the necessity for the fullest possible use of such land as is available, with its great population (estimated at between 2 and 2½ millions and increasing at more than 70,000 per annum) crowded into a mere 400 square miles of the Earth's surface. There is the sharp contrast between the crowded urban areas of Hong Kong and Kowloon and the rural districts of the New Territories. Serious problems arise from the mountainous nature of much of the area and from the heavy, often torrential, rainfall which is largely responsible for the soil erosion that has created the 'badlands' of the open hillsides.

Dr. Tregear has tried to bring together the basic data necessary for the use of planners and administrators, and to indicate the sources from which fuller information can be obtained. His is a factual survey, a record of things as they are, not a forecast of possible developments nor a catalogue of suggested remedies for the territory's land-use problems. This is exactly as it should be and it is indeed the justification for all land-use surveys. They may be difficult to carry out and they may sometimes seem very wasteful of time and energy ; yet without them there can be no precise and objective assessment of land use as it can be observed to-day. Subjective judgments, wishful thinking and intelligent anticipation are all specifically excluded from the purpose of the World Land Use Survey.

In essence, Dr. Tregear's monograph is an exposition and elaboration of the land-use map prepared. At times the literary style is weak, and occasionally the text becomes little more than a series of notes. A few of the diagrams are disappointing because they cannot be read easily or have been excessively reduced. Sometimes Dr. Tregear might have emphasized more those relationships of physical and human phenomena that geographers claim as a special part of their field. There may well be monographs with a rather more penetrating analysis later in this series. Nevertheless, the volume deserves a welcome by geographers and others both for its own worth and as an indication of what may be expected for other areas in the future. It is a sign that the World Land Use Survey has passed beyond the talking and planning stages and, in some countries at least, beyond the field-work to the point where maps and reports are being produced. Clearly the editor, Prof. Stamp, who has just retired from his chair in the University of London, is going to be as active as ever in the years to come. We can, therefore, anticipate a series of regional monographs for the world that will be comparable in conception, content and importance to the well-known County Reports of the Land Utilisation Survey of Britain.

THE FRESHWATER BIOLOGICAL ASSOCIATION

BESIDES details of the administration, organization and state of the finances of the Freshwater Biological Association for 1957–58, the twenty-sixth annual report contains a statement by the Director on the scientific work of the staff.

In the chemistry section analyses of algae have shown that cobalt, copper and zinc are present in the plant tissues in amounts the ratios of which are similar to those of their concentrations in the environment, a fact which suggests that the uptake of such elements by algae may be governed rather by their concentrations in the surrounding water than by any physiological needs of the plant.

Earlier work on the acid waters of blanket bogs in the Pennines and of bog lakes in Nova Scotia suggested that both owed their acidity to sulphuric acid. Dr. E. Graham has now extended these studies to bog waters elsewhere in Britain and in less-oceanic sites in Poland with similar results. Since sulphuric acid also seems to cause the acidity of the soil solutions extracted from heavily leached mor humus layers overlying podzolic soils in Lake District oak woods, it is probably to be regarded as an important agent in soil leaching. While in Britain it comes largely from atmospheric pollution brought down in rain, there is evidence that it is also produced by the breakdown of organic sulphur compounds in the soil ; it may therefore be important in unpolluted areas also.

Continuing his observations on the fluctuations in numbers of the smaller nannoplankton, Dr. J. W. G. Lund finds a clear difference between the periodicity of the very small green algae in the surface waters of Windermere, Esthwaite Water and Blelham Tarn and that of the larger species. Thus, large populations of the small forms have been observed in late winter and early spring. It will, however, be necessary to continue observations over several years to determine whether this happens regularly.

Work on the polycentric chytrids which occur in the reed beds of Windermere has been continued by Dr. L. G. Willoughby, who is making a comparative study of eight isolates of *Cladochytrium replicatum*. So far, particular attention has been paid to growth-rates and fruiting (that is, zoosporangium formation) on agar. One of the isolates has been uniformly sterile under all conditions, while another has only rarely formed zoosporangia. Two further isolates of the eight can be segregated not only on purely morphological grounds, but also because the rate of linear growth on agar is consistently high. The effect of light on growth and fruiting in this fungus has been investigated. Light is not essential for pigment and hence zoosporangium formation, and total growth, as measured by the increase in colony diameter on agar, is independent of this factor. It seems clear, however, that fruiting is generally greater in light than in the dark, the effect being particularly noticeable in the isolates with high fruiting capacities.

A further study has been made of the influence of the container on the rate at which bacteria multiply in samples of lake water stored in the laboratory. This has been extended to cover polyethylene and nylon containers as well as those of silica, 'Pyrex' and soda-glass. The conclusion reached previously that silica provided the least 'active' surface for bacterial growth was confirmed ; the others follow in the order 'Pyrex', soda-glass, polyethylene up to nylon, which stimulates the largest bacterial growths. It appears that the surface properties of polyethylene and nylon in particular facilitate the supply of something the bacteria need, whereas silica has no such property, regardless of the type of water, the temperature, or of whether the containers are stationary or shaken. This is borne out by the discovery that in experiments using a constant circulation of water, considerable multiplication of bacteria took place wherever the liquid remained in contact with polyethylene or nylon connecting tubes. These results may have direct practical importance on industrial process problems, where polyethylene pipes become blocked by masses of slime-forming bacteria attached to the walls, and in the storage of non-sterile solutions in containers made of these materials.

The use of opercular bones to estimate the age and past growth of pike has been further investigated by Dr. Winifred Frost and Miss Charlotte Kipling, who concluded last year that growth can be calculated accurately by simple proportion from measurements of the annual rings, making an arbitrary choice by inspection of a centre from which to make the measurements. Since the rings near the centre are not always clearly visible, the method does not give reliable estimates of growth in the early years of life. This difficulty has been overcome by the use of theoretical growth-tables derived from Ford's growth formula, using data from Windermere calculated for slow-, medium-, fast- and very fast-growing fish for the two sexes separately. By comparing the growth in later years of any individual fish with these tables, it is usually possible to assign it to one of the growth-rate categories. This makes it possible to infer its true age and so to decide whether the first discernible ring represents its first, second or third winter.

D. F. Westlake has measured the rate of production of oxygen by *Ranunculus* spp. in a closed, static system, at various light intensities. The highest gross rate of oxygen production found for light-saturated plants was about 10 mgm. of oxygen hr./gm. (dry weight) at 15° C. Light-saturation was approached at 10,000 lux, and both this and the maximum rate of oxygen production are lower than generally reported in the literature on higher plants. Possibly this is the result of using static conditions for the experiments, and apparatus for determining oxygen production in flowing conditions is being developed.

MECHANICAL ENGINEERING RESEARCH LABORATORY

REPORT FOR 1957

THE report on the work of the Mechanical Engineering Research Laboratory for 1957* makes fascinating reading, and contains much that will interest any engineer and many physicists.

The chairman of the Engineering Research Board directs attention in his report to the difficulty of getting the results of the Laboratory's work both disseminated and applied. Most engineering scientists have yet to learn that a paper which may lead in due course to scientific honour is unlikely to be understood by many practising engineers, however high their theoretical attainments; the work must also be published as a straightforward physical description, written in lucid English and devoid of mathematics if it is to be read and applied. Sir Charles Inglis used to state this truth regularly in his lectures; few have learned the lesson.

The proportion of scientific and experimental staff is 160 out of a total of 444. This seems high. Does the Laboratory suffer from the difficulty common in Government and university laboratories of being hamstrung financially in providing adequate ancillary and office staff?

In recommending a rapid expansion of the Laboratory, the problem of how it, the universities and the colleges of advanced technology are all to be staffed must arise. In Germany, most of the work similar to that done at the Mechanical Engineering Research Laboratory is done in institutes of the Technische Hochschulen. Might it not be better to give the colleges of advanced technology similar institutes?

While it is clear why some of the research, both fundamental and applied, is being done nationally, it is surprising to find that fundamental work on greases has not already been undertaken on an adequate scale by private industry. When such gaps are found, is it not desirable that they should be investigated where the staff concerned can also be available for part-time teaching?

Nevertheless, the report describes the development of fine facilities and the accomplishment of much excellent work. Many firms should read it and send members of their staff to see what is being done.

TILT CRITERIA AND DIRECTION OF ROTATION OF SPIRAL GALAXIES

G. DE VAUCOULEURS has a paper with the above title in the *Astrophysical Journal*, 127, 2; March 1958, in which he presents a review of the observational evidence on the direction of rotation of the spiral pattern in ordinary and barred spirals. A growing body of evidence suggests that the formation of spiral structure is governed by the large-scale magnetic and hydrodynamical properties of the interstellar medium in rotating galaxies, and according to current ideas, dust or 'smoke' particles may form out of the gaseous medium and induce the condensation of gas clouds into stars or groups of stars. The author of the paper has discussed the morphology of spiral structure and its bearing on the large-scale instantaneous distribution of gas and dust in galaxies (*Hand. Phys.*, 53), and in the present paper he deals with the systematic motion of the interstellar substratum on the largest scale in a galaxy, in other words, with the general rotation of the spiral pattern. The previous investigations of those who have devoted their attention to this subject—Baade, Hubble, Lindblad, Stebbins, Zwicky and others—are referred to, and the reasons for the divergences in the interpretations are analysed. The discussion is recapitulated in Table 1, p. 499, which consists of eleven columns (the symbols used in these are explained at the end of the table and also on the previous page) and the conclusions are briefly as follows.

Comparing this table with similar tables of Hubble published in 1943 it appears that of the fifteen objects in his Table 1, "Well Observed Nebulæ", six are in common with the present discussion, and the conclusion that the arms are trailing in the rotation appears unequivocally confirmed by one or several of the primary or secondary criteria. Of the eight objects in Hubble's Table II, "Doubtful Cases", five are in common and three have been removed from the doubtful class by the application of one or several of the same criteria. *NGC* 5005, which was doubtful only in respect to the sense of spectroscopic rotation given by Slipher, has now been confirmed by Mayall, and the last one (*NGC* 4594) is indecisive. It is pointed out in Appendix I, however, that in 1951 Lindblad attempted to unravel the direction of its spiral pattern by means of a geometric restoration in the plane of the spiral of the distribution of bright knots measured on a photograph in ultra-violet light with the 200-in. reflector. Fig. 9*a*—Lindblad's interpretation—is not unambiguous, and an alternative interpretation (*b*) of the distribution appears at least as plausible,

VISUAL PIGMENTS OF THE OCTOPUS A

By PAUL K. BROWN and PATRICIA S. B

Biological Laboratories of Harvard University, Cambridge, Mass., and

THE first molluscan visual system to be examined chemically was that of the common squid, *Loligo pealii*. This animal possesses a rhodopsin comparable with that found in vertebrate rods, composed of neo-b retinene joined to the protein, opsin[1,2]; but under physiological conditions, squid rhodopsin engages in a more limited series of reactions than occur in the vertebrate retina. In vertebrate rods, rhodopsin bleaches in the light, over the transient intermediates lumi- and meta-rhodopsin, to a mixture of retinene and opsin; then retinene is reduced to vitamin A. In the squid retina, the little vitamin A that is present seems to take no immediate part in the visual processes[3]; and light does not normally bleach rhodopsin, but converts it to metarhodopsin. Vertebrate metarhodopsin is highly unstable, hydrolysing rapidly to retinene and opsin; but squid metarhodopsin is stable, the retinene remaining attached as chromophore to opsin. The change from rhodopsin to metarhodopsin involves only the isomerization by light of the chromophore retinene from the neo-b configuration (11-*cis*) to all-*trans*. Light also causes the reverse isomerization, from all-*trans* to neo-b. That is, in the squid retina light brings into a steady state the system:

$$\text{rhodopsin} \overset{\text{light}}{\rightleftharpoons} \text{metarhodopsin} \quad \text{(ref. 2)}$$

This pair of reactions, which only introduces the rhodopsin system in a vertebrate, is the entire system of the squid.

A period spent at the Stazione Zoologica in Naples afforded us an opportunity of working on the visual systems of the octopus (*Octopus vulgaris*) and cuttlefish (*Sepia officinalis*). The animals were dark-adapted 8–10 hr., and the retinas dissected out under red light, and frozen. After thawing, the tissue was ground in a cold mortar in 40 per cent sucrose (w/v). to light at *p*H 9 and 2° C., *Sepia* and psins were converted to the correspond- psins. The spectra of these substances, H 9, 7 and 5, showed that they are *p*H in *Loligo*[2]. In alkaline solution, the s of all three organisms have $\lambda_{\max}$. In acid solution these substances coloured, apparently through adding a of the acid metarhodopsins are a little ch organism (Table 1). These changes ersible. The absorption spectra at all hibit a common or isosbestic point, they represent stoichiometric inter- tween a specific initial and a specific his appears to involve, as in *Loligo*, the

Top, right: rhodopsin, liddle row: metarhodopsin, formed by irradiating is is a *p*H indicator, going reversibly between an $\lambda_{\max}$ 380 mμ) and an acid form ($\lambda_{\max}$ 503 mμ), her extinction than rhodopsin. Bottom row: the has been converted to 'indicator yellow' by h acid. This changes in colour with *p*H, going ted Schiff base in acid solution ($\lambda_{\max}$ 443 mμ) to a retinene and denatured opsin in neutral solution , and to an indiscriminate mixture of Schiff base en retinene and opsin in alkaline solution ($\lambda_{\max}$. e end of these procedures, the product was treated mine to convert all retinene to retinene oxime; sulting spectrum is shown at the top, left

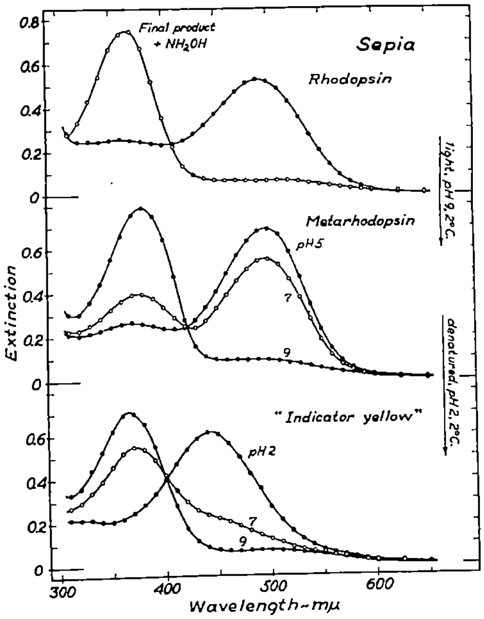

Fig. 2. Visual pigment of the cuttlefish. Top, right: rhodopsin ($\lambda_{\max}$ 492 mμ). Middle row: metarhodopsin at *p*H 5, 7 and 9. Bottom row: 'indicator yellow' at *p*H 2, 7 and 9. In this instance it appears that the acid denaturation of metarhodopsin was not wholly completed, and this accounts for some distortion of the spectra of indicator yellow, particularly at *p*H 7. The appearance of a common or isosbestic point in the spectra of indicator yellow is also a fortuitous result of this distortion. At the end of these procedures the product was treated with hydroxylamine to convert retinene to retinene oxime; the resulting spectrum is shown at the top, left

metarhodopsin is 28 mμ longer than that of rhodopsin, so that when *Octopus* rhodopsin is irradiated it changes in colour from orange to red.

In rhodopsin the aldehyde group of retinene appears to be combined with a specific amino-group of opsin in a Schiff base linkage:

$$\mathrm{C_{19}H_{27}CHO + H_2N\text{-}opsin} \rightarrow \mathrm{C_{19}H_{27}CH{=}N\text{-}opsin + H_2O}$$

To explain the colour, it is assumed that this has added a proton, the charge of which induces a greatly increased resonance in the conjugated system of retinene: $\mathrm{C_{19}H_{27}CH{=}NH^{+}\text{-}opsin}$; and supposes also that a close steric fit between the hydrocarbon portion of the retinene molecule and the protein, permitting a high degree of interaction between the two, further enhances the resonance[6]. In metarhodopsin (acid form), much the same situation obtains, except that retinene has gone from the neo-b to the all-*trans* configuration; this also appears to be a protonated Schiff base, its spectrum still enhanced by the steric fit between retinene and opsin[2].

The metarhodopsins were now denatured by being brought to a high acidity (*p*H 2–3). We shall call this product 'indicator yellow'. With the denaturation of opsin, the fit between it and all-*trans* retinene is lost, with a corresponding loss of colour. The $\lambda_{\max}$ falls to 443 mμ, the position found in a variety of model Schiff bases of retinene when acidified[7]. The retinene is probably still attached to the original amino-group (the "N-retinylidene opsin" of Morton and Pitt, yet with denatured opsin); but on neutralization of the solution, it hydrolyses off, to yield free retinene and denatured opsin[8]. The $\lambda_{\max}$ of these preparations, brought to *p*H 7, is therefore that of free retinene, about 385 mμ. (In Fig. 2 this spectrum is distorted by the presence of a residue of metarhodopsin.) On making such a solution alkaline (*p*H 9), retinene recombines with amino-groups, not only at the original site, but indiscriminately, to form a variety of Schiff base linkages with $\lambda_{\max.}$ 367 mμ (ref. 7). These changes are thereafter reversible.

At the close of these procedures, hydroxylamine was added to the solutions, converting all the retinene present to retinene oxime ($C_{19}H_{27}CH{=}NOH$). The resulting spectra are shown at the top (left) of Figs. 1 and 2. From the relative extinctions of rhodopsin and the retinene oxime derived from it, and the known molar extinction ($\varepsilon_{\max.}$) of retinene oxime (51,600), the $\varepsilon_{\max.}$ of the rhodopsins can be computed (Table 1)[8]. For both *Sepia* and *Octopus* this comes out to be about 37,000, slightly lower, though perhaps not significantly, than cattle or *Loligo* rhodopsin (40,600)[9].

In summary, these measurements agree very well with the earlier measurements on *Loligo* rhodopsin, and their analysis by Hubbard and St. George[2]. It is of some interest that these three cephalopods represent two sub-orders and three families: the Decapoda, which include the squid and cuttlefish in separate families, and the Octopoda.

The rhodopsins of these cephalopods demonstrate a condition that has already become familiar in vertebrate rhodopsins: a considerable spread of absorption spectra, $\lambda_{\max.}$ ranging from 475 to 493 mμ. In these animals as in the vertebrates this variation results from the fact that though all known rhodopsins have the same chromophore, neo-b retinene, each species of animal possesses a different opsin; and with this go differences in the absorption spectrum and other properties.

In all three cephalopods, the actio
rhodopsin yields a relatively stable n

A TEMPLATE MODEL FOR THE SYNTHESIS OF RIBONUC ACID FROM DEOXYRIBONUCLEIC ACID

By Dr. GEOFFREY ZUBAY*

Medical Research Council Biophysics Research Unit, King's College, University of London

THE suggestion has been made that the nucleotide composition of nuclear ribonucleic acid could be accounted for by assuming that the nuclear ribonucleic acid is synthesized on a double helical deoxyribonucleic acid template with each base pair providing a specific site for a nucleotide of ribonucleic acid[1]. The two alternative possibilities to which one is led by these chemical data are listed in Table 1, where *A–T* 1 refers to the deoxyribonucleic acid base pair with adenine on chain 1 of the double helix and thymine on chain 2, and *A–T* 2 to the reverse situation. If this scheme is correct, it might be possible to determine the actual sites on the template by examination of molecular models, and it is the purpose here to discuss the results of a systematic investigation of molecular models.

Initially, let us consider some of the general requirements of a template which we define as a system capable of producing a polymer with a specific linear sequence of monomers. We shall take the
problem of deoxyribonucleic acid syr

nucleotides. We have concluded that the success of the deoxyribonucleic acid template is at least partly due to the fact that the hydrogen-bonded base pairs, adenine and thymine, guanine and cytosine, are identical in so far as they may be fitted into a completely regular double helix structure. If we visualize the process of polymerization involving the template the advantages of this structural regularity becomes clear. Consider a single chain of deoxyribonucleic acid acting as a template and a second growing chain partly formed on it; then, where a second chain is formed, the resulting double chain polynucleotide would probably coil up into a helical structure identical with deoxyribonucleic acid because this would be the energetically favourable situation. If we now add a monomer to the growing chain, and adenine is the first unpaired base on the template, either guanine or thymine could form the same pair of hydrogen-bonds with it. However, due to the deoxyribonucleic acid-like configuration of the polynucleotide chain to which we expect the monomer to add, only thymine can hydrogen-bond favourably with adenine and still have its reactive sugar phosphate group in a position where addition to the growing chain is possible (regardless of the intermediate chemical steps involved). Thus, only thymine is capable of becoming a permanent component in the growing polynucleotide chain when the opposing base on the template is adenine. A similar argument would apply to the other bases. In summary, we see that the specificity of the deoxyribonucleic acid template site (apart from enzymes involved) involves at least two conditions: (1) energetically favourable binding of its monomer nucleotide counterpart; (2) binding in such a way that the reactive group of the bound monomer is in a position to condense on the growing end of the polymer chain.

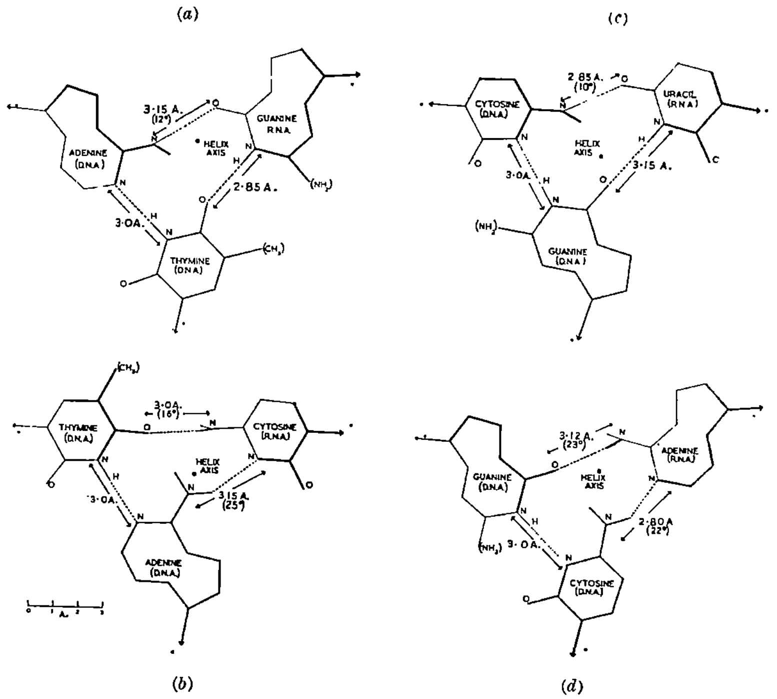

Fig. 1. Nucleotide triplets which may be involved in the template

I have attempted to find specific sites for the binding of the four commonly occurring ribonucleotides to the deoxyribonucleic acid base pairs which would satisfy requirements similar to the two just discussed. Initially, I sought specific sites for binding ribonucleotides to the deoxyribonucleic acid in its normal double helical configuration. However, it was not possible to satisfy conditions (1) and (2) simultaneously and, therefore, I have concluded that deoxyribonucleic acid is not capable of acting as a template for ribonucleic acid synthesis without undergoing major configurational changes. Indeed, only one type of modification in the deoxyribonucleic acid molecule has led to a molecular model in which we could approximately satisfy our two conditions. This modification involves three steps: the breakage of hydrogen-bonds between the amino-group and the carbonyl group in both base pairs of the deoxyribonucleic acid; the twisting of the planes of the bases relative to one another; and, in some cases, a rotation of the adenine and cytosine amino-groups out of the plane of the base. (A similar change has been described in more detail for the synthetic complex, polyadenylic acid/2 polyuridylic acid[3].) Together with these alterations in the bases, adjustments in the configuration of the sugar phosphate backbone becomes necessary; nevertheless, I shall leave these unspecified at present. The systematic breakage of the amino-carbonyl hydrogen-bonds leaves the two deoxyribonucleic acid chains still connected by NH . . . N hydrogen bonds. If we now consider the binding of ribonucleic acid base groups by this system, there are in all eight nucleotide triplets we must inspect. First, we have attempted to build identical hydrogen-bonded triplets (identical being used in the same sense as before) using the four triplets that would occur in the code suggested from the chemical data in Table 1. In Fig. 1 we see the outcome of this attempt. The base triplets are shown in two-dimensional projection. The bases are represented by light, medium and heavy lines to illustrate that they are respectively, below, in or above the plane of the paper. In all cases, the deoxyribonucleic acid base on chain 1 is drawn in the plane of the paper, and the other two bases are tilted from the plane of the paper by about 18°. The helix axis is perpendicular to the plane of the paper; its indicated position is only approximate. (I have arbitrarily chosen the tilting arrangement in the figures since it would be possible to tilt in the reverse fashion, by taking the mirror image in the plane of the paper. Probably when the problem of wrapping the triplets into a helical structure is considered in more detail, regular tilting of one sort would be favoured.) The arrows attached to the nucleotides represent the connecting link to the C_1 atoms of the sugar. The dots near these arrows represent the average positions of the C_1 atoms for the four triplets and it can be seen that the maximum deviation from this average is 0·5 A. The hydrogen-bond distances, N—H . . . X, are indicated in the figures, and the deviation of the N—H . . . X angles from linearity is indicated in

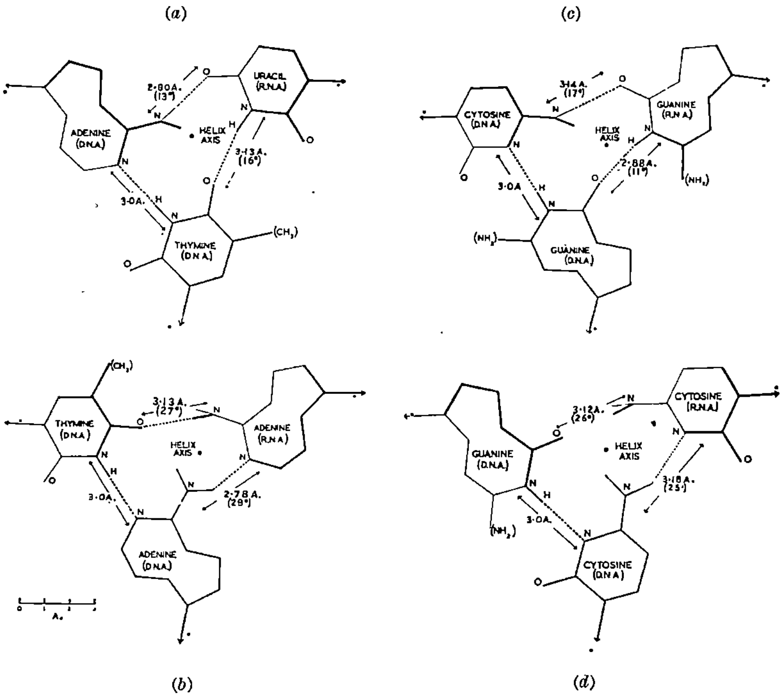

Fig. 2. Nucleotide triplets which might interfere with the template

parenthesis below the hydrogen-bond distances. I have used the limits suggested by Donohue[4] for the hydrogen-bond lengths and I have restricted the deviation of the N—H . . . X angle from linearity to 28°. Within these limits it has not been possible to make the four triplets identical. Nevertheless, it seems likely that it would be possible to construct a fairly regular three-stranded helical model with reasonable van der Waals contacts using the triplets in Fig. 1 more or less interchangeably. Thus, the template model suggested by Fig. 1 is structurally reasonable and consistent with the chemical data in Table 1. Consequently, a three-stranded helical molecule involving the triplets in Fig. 1 could be an intermediate complex in the synthesis of nuclear ribonucleic acid.

CONTROL OF LECITHINASE ACTIVITY BY THE ELECTROP CHARGE ON ITS SUBSTRATE SURFACE

By A. D. BANGHAM and R. M. C. DAWSON

Agricultural Research Council Institute of Animal Physiology, Babraham, Cambridge

It has been shown that a preparation of the phospholipase (lecithinase) from *Penicillium notatum* which normally only hydrolyses lyso-phospholipids will also attack lecithin providing this substrate contains small amounts of an activating lipid, such as monophosphoinositide or polyglycerolphospholipid[1]. The addition of these activating lipids to lecithin caused a marked reduction in the extent to which the lecithin was extracted from aqueous emulsions by lipid solvents such as ether, a property which ran closely parallel to the developme
activity[2]. This suggested that the
connected with some change in th
lecithin particles. It was, theref
examine the particles by microelectro
determine the sign and magnitude
phoretic charge.

Ovolecithin was isolated by chr
alumina and silicic acid columns a
viously[2], and emulsions were exami

electrophoresis cell of the type developed by Bangham, Flemans, Heard and Seaman[3]. The lecithin particles were found to have a net zero charge from pH 3·0 to 13·0 when emulsified in 0·145 M sodium chloride. In formate buffer at pH 3·3 which was optimal for enzyme activity, the particles had a small positive charge. On the addition to the lecithin of a small percentage of certain lipids which had previously been found to activate its enzymic hydrolysis (monophosphoinositide and cardiolipin), the lecithin particles acquired a net negative charge. It seemed likely that the reason for this was that these activating lipids possess a negative polar group in the tertiary dissociable hydrogen atom of the phosphate moiety which is not compensated for by a positively charged basic group. It was consequently expected that any molecules possessing a hydrophobic portion and a negatively charged polar group (amphipathic) would also render a lecithin surface susceptible to enzymic attack. It was shown that dicetylphosphoric acid, taurocholic acid and dodecyl sulphate also activated the enzyme system and produced a net negative charge on the lecithin surface at pH 3·3. The latter compound, however, would only activate the lecithinase within a comparatively narrow range of concentration.

With the activators so far studied, it was necessary to add a certain critical concentration to the lecithin before enzyme activity began. As the concentration of activator was further increased, the lecithinase activity rapidly reached a maximum, and with the further addition of activator there was a decrease in the amount of lecithin hydrolysed by the enzyme. At the concentration at which activation commenced, the lecithin had acquired a net negative electrophoretic charge which was approximately the same when either dicetylphosphoric acid or cardiolipin was used as the activator. This suggests that a certain critical negative charge density on the lecithin surface may be necessary for the commencement of the enzymic attack.

Evidence substantiating the theory that a negatively charged lecithin surface is necessary for enzyme action was obtained by studying its inhibition by metal ions such as UO_2^{2+}, Th^{4+}, and Ca^{2+}, which are efficient counter ion-binders of the negative groupings on a lipid surface[4]. Using a lecithin surface activated with dicetylphosphoric acid, it was shown that at the exact concentration of these ions necessary to neutralize the charge on the lecithin surface, the inhibition of enzymic activity became complete. In further experiments, positive amphipathic molecules were introduced into a negative surface of lecithin plus dicetylphosphoric acid particles by the gradual addition of cetyltrimethylammonium bromide, and here again there was a similar 'cut off' of enzymic activity just before the point at which the surface changed from being negatively charged to positive.

The question remained as to whether the negative charge on the surface of the substrate activated the actual attack of the enzyme on the lecithin surface or whether it merely solubilized the substrate by a detergent-like action, the subsequent enzymic attack occurring in the bulk phase. Microscopic examination of lecithin emulsions and high-speed centrifugation suggested that some dissociation of the lecithin particles into smaller micelles did occur with increasing concentrations of activator. However, there appeared to be no connexion between this more efficient emulsification and the development of the enzymic attack. Proof that the negative groupings were directly concerned with the actual enzymic attack on a lecithin surface was obtained by using surface films of yeast lecithin of high specific activity labelled with phosphorus-32. These films were introduced on the surface of a formate buffer at pH 3·3 and the counts per minute coming from the surface recorded with a mica end-window β-counter. The buffer was stirred magnetically from the underside so that any water-soluble glycerylphosphorylcholine produced by enzymic activity would be distributed throughout the bulk phase and its phosphorus-32-counts not recorded. With pure lecithin films injection of the enzyme into the bulk phase produced no change in the counting rate. When films were prepared from lecithin labelled with phosphorus-32 mixed with a small percentage of activator (for example, dicetylphosphoric acid, cardiolipin), there began a steady loss of radioactivity from the surface within a few minutes of the introduction of enzyme into the formate buffer. This loss was largely prevented by the addition of 0·02 M sodium fluoride to the bulk phase, a concentration which is sufficient to inhibit the enzyme almost completely. The loss of radioactivity was also not observed when the pH of the buffer was changed to 4·4, which is away from the optimum for enzyme activity. These experiments indicate that the enzyme acts directly on the activated surface of the lecithin film since any reaction occurring in the bulk phase would not be recorded by a change in the counting rate.

So far as we are aware, this is the first time that the activity of an enzyme has been directly related to the electrical (electrophoretic) charge on its substrate surface. The mechanism by which the lecithin surface becomes active when a critical density of negative polar groups is reached is not clear. Electrophoresis measurements on paper show that the enzyme is isoelectric at pH 3·3 so that the activation effect of the negative groups would appear to depend on orientation of the enzyme molecule within the diffuse ('double') layer rather than on simple electrostatic attraction and adsorption. This conclusion is supported by an observation that in the presence of the enzyme the lecithin surface remains negative, whereas, as is generally known, the non-specific adsorption of a protein at its isoelectric point on a negative surface leads to a masking of the charge.

In the inhibition experiments with metallic ions, it was observed that at concentrations of Th^{4+} or UO_2^{2+}, which were just insufficient to inhibit the enzymic activity, there was a distinct stimulation of the lecithinase action. This suggests the possibility that the metallic ions may initially mask negative groupings on the enzyme molecule itself, which would further assist the enzyme to orientate itself in relation to a negatively charged lecithin surface. If this is so, it would help to explain why the 'cut off' of enzymic activity with increasing amounts of these metal ions occurred when the lecithin surface was electrically neutral rather than at the critical negative charge density necessary for the development of enzymic attack. It is proposed to publish a fuller account of this work at a later date.

Fall-out Radioactivity in a Deer's Antlers

The accumulation of radioactive material in biological structures as a result of fall-out from nuclear explosions presents a continuing and increasing problem in relation to human food supplies. It is now well established[1,2] that radiostrontium-levels in the bones of children are higher than in adults, and this is clearly related to the rate of deposition of 'new' calcium in the skeleton. The rapidity with which the antlers of deer are formed, coupled with the fact that these animals normally graze on upland pastures which are known to contain relatively high levels of fall-out radioactivity[1], suggested that antlers might well show particularly heavy contamination with radiostrontium. An opportunity was therefore taken during the course of a survey of radiostrontium-levels in foodstuffs to include for assay a pair of antlers from a deer shot on the island of Islay on November 3, 1957.

One complete antler was ashed, a strontium separation carried out with added carrier and the activity measured on a Geiger–Müller counter. The activity (strontium-89 plus strontium-90, and possibly active traces of other alkaline earths and heavy metals) was found to be 126 $\mu\mu$c./gm. of calcium present. At about the same time, a transverse section 2 mm. thick was cut from the other antler of the pair at one of the points of branching and applied in close contact with a piece of 'Kodirex' X-ray film. This was then exposed for 82 days in a light-tight box and the resulting autoradiogram is shown in Fig. 1.

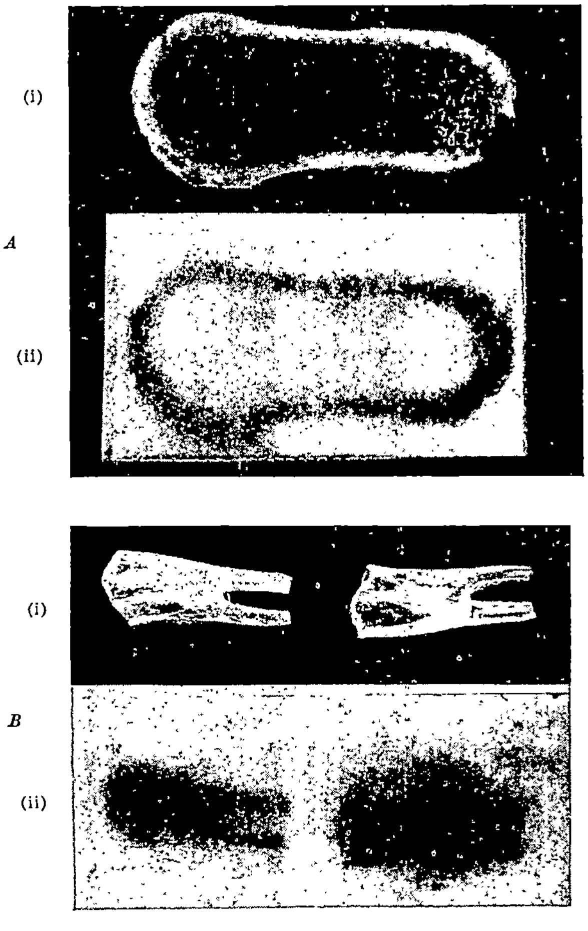

Fig. 1. *A*, Cross-section of deer's antler (i) and autoradiogram produced from it (ii). *B*, Two halves of a sheep's premolar from Ben Lawers, Perthshire (i) and the corresponding autoradiogram (ii)

A check on the distribution of activities between the two obvious concentric zones of the section was made by separating these two regions from a 2-in. length of the same antler and recovering the strontium from each. The results showed an activity in the dense peripheral zone of about nine times that in the central zone of spongy material, per unit area of cross-section.

We were later able to obtain a pair of antlers from a deer shot in the same area in 1952 for use in a control experiment. The strontium activity of this sample obtained by the same method as before was 11·2 $\mu\mu$c./gm. of calcium. Exposure of a similar section from these antlers to X-ray film for a period of 92 days produced a very slight image which was insufficient to allow photographic reproduction. It is therefore concluded that the major part of the blackening on the original autoradiogram is due to the longer-lived fall-out elements, in particular to the strontium isotopes.

We have since obtained autoradiograms of other biological structures, including a premolar of a sheep found dead at about 1,700 ft. on the side of Ben Lawers, Perthshire (see also Fig. 1) and of grass from the same area, which is known (unpublished work by Hawthorn, J., Stanwix, P. R., and Duckworth, R. B.) to contain high levels of radioactive strontium. We are not aware of the previous publication of autoradiograms of biological structures due purely to general fall-out radioactivity.

Our thanks are due to Dr. McGowan of Callumkill, Island of Islay, for supplying the antlers.

Accumulation of Strontium-90 in Dental Tissues

Weanling rabbits given single injections of 500–1,000 μc. strontium-90 per kgm. showed a high frequency of tumours of the jaw[1], and preliminary histological studies suggest that they arose in close relation to the teeth. The amount of strontium-90 accumulated in individual teeth and in all teeth of one upper quadrant of the jaw after a single intravenous injection of 100 μc. strontium-90 per kgm. is given in Table 1. The amount of strontium-90 in the teeth is seen to increase with time after injection for at least thirty days and then to fall abruptly. The teeth of the rabbit grow continuously, and strontium-90 is lost because the layers in which the strontium is initially deposited erupt into occlusion and are later worn away in mastication. A similar

Table 1. STRONTIUM-90 IN TEETH AND FEMUR

sudden loss of strontium-90 from the teeth of the rat may be seen autoradiographically[2].

The initial increase with time after injection in the amount of strontium-90 in the teeth is in marked contrast to the steadily decreasing amount of strontium-90 in the femur (Table 1). This difference in behaviour between tooth and bone may be due to the substantial remodelling which occurs in bone but not at all in teeth, or because ion exchange in the mineral of bone is much greater than in the mineral of the teeth. In either case the liberation of strontium-90 from bone into the blood stream, during the days and weeks after a single intravenous administration, provides a continuously available source of strontium-90 for incorporation into the actively calcifying teeth, so that their strontium-90 content continues to increase with time until the moment when the first deposit reaches the masticatory surface and begins to be worn away. Thus the intensity with which the jaw is irradiated by a local radioactive deposit in the teeth may well be quite unrelated to general levels of deposition in bone.

This may be specially important in species like man, where the teeth do not wear away to the same extent as, and where strontium-90 incorporated into calcifying teeth will be much more permanently fixed than, in rodents.

Shifts of Arc Lines at Various Pressures in Magnetic Fields

AN investigation of certain spectral lines emitted in a high-voltage arc between brass electrodes in nitrogen gas was made under pressures of from 1/7 to 85 atmospheres. The arc was run in and out of a magnetic field of 4,000 gauss. An empirical relation between the shift with and without a magnetic field at varied pressures for nine spectral lines has been found. There was a certain amount of scatter in the shifts of the lines, but among the hundreds of measurements of the spectral lines studied from Eastman Kodak spectrum analysis No. 2 plates, a significant pattern of shifts was found which differed for emission in a magnetic field from emission in a non-magnetic field.

Although the shift of any particular arc line under pressure is not steady the emergent pattern is quite evident. In all cases, the shift due to pressure in a magnetic field is less than in a non-magnetic field. With the exception of the first principal lines of copper, the shift of which seems to be anomalously changed by the magnetic field, lines most shifted by the pressure are most affected by the magnetic field.

In Fig. 1 pressure shifts of spectral emission lines of zinc, copper and lead in a magnetic and non-magnetic field are shown. It is apparent that, in addition to a decreased pressure shift in a magnetic field, the slopes of the lines for pressure shift versus pressure are less steep for emission in a magnetic than in a non-magnetic field. The ^3P–$^3P'$ lines of lead are an exception. Even for lead, the slope is not greater in a magnetic field. Lead lines were the only ones considered for which the coupling was *j*–*j*.

These results give considerable support to the theory that the normal van der Waals forces responsible for pressure shift are counteracted in a magnetic field by

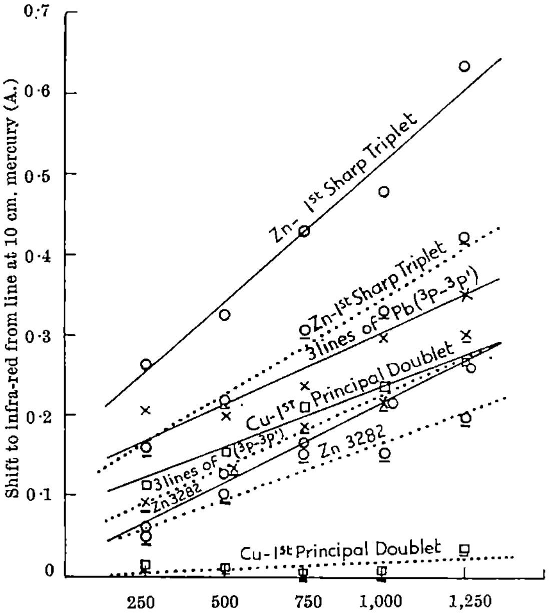

Fig. 1. Pressure shifts of arc lines: – – –, in the presence; —— in the absence of a magnetic field. Curves are straight lines of best fit, through averaged points determined for zinc, ○; lead, ×; and copper, □. Underlined symbols refer to measurements in a magnetic field

space-charge forces. In a magnetic field, electrons and ionized metal gas ejected from the electrodes follow different paths between the high-voltage (5,000-V. a.c.) electrodes. It is suggested that a space charge made up of ions of vaporized metal is present in the space of the discharge when a magnetic field is applied. The magnetic field is perpendicular to the electric field between the electrodes. Motion of the charged particles is reversed by the a.c. electric field 120 times per second. In their much slower acceleration from zero velocity, the positive ions are diffused more than electrons by the force of the magnetic field transverse to their direction of motion.

The effect of the positive space charge is to increase the energy of electron transitions responsible for the spectral lines. The negative electronic charge belonging to an atom about to emit radiation is drawn farther from the nucleus by the surrounding positive-ion plasma. Pressure-shifted emission lines with a magnetic field will be to the violet side of pressure-shifted emission lines without a magnetic field.

Space-Charge Limited Currents in Insulating Materials

The modern theory of solids predicts that an electron can travel freely through the periodic potential field of a perfect crystal lattice provided that its energy lies within certain well-defined limits, or energy bands, which are characteristic of the crystal. A practical implication of this is that, if a sufficient number of such 'free' electrons can be introduced from a metal cathode into the allowed bands of an insulating crystal, it should be possible to obtain a space-charge limited current flowing through the crystal. Such a current flow would be analogous to the space-charge limited current which flows across the evacuated region between the cathode and anode in a thermionic vacuum diode.

Previously, two circumstances in the main have prevented the observation and subsequent exploitation of space-charge limited currents in insulating crystals. First, the presence of surface potential steps, due mainly to differences in magnitude between the work function of the metal cathode and the electron affinity of the crystal, have prevented the bulk introduction of electrons from the metal into the allowed bands of the crystal. Secondly, even the best crystals it is possible to grow contain lattice defects which act as trapping states and trap any initial electron flow to produce a fixed space-charge field which builds up to oppose further current flow.

Although the exploitation of space-charge limited currents in insulating materials has not yet been achieved, several theoretical studies of the anticipated characteristics of such currents have been reported. In particular, by neglecting the influence of thermal diffusion of electrons, trapping states, residual small concentrations of donor centres, and the influence of the anode electrode, Mott and Gurney[1] have shown that the space-charge limited current density should be given by $J = 9\varepsilon\nu V^2/8d^3$ amp./m.², where ε is the absolute permittivity and d is the thickness of the insulator, and ν is the mobility of the electrons in the insulator. At sufficiently high applied voltages the whole of the space-charge in the insulator should be drawn across. The current should then become proportional to voltage, since the drift velocity of the electrons would be proportional to the applied field. Under these conditions the current density should be given by $J = e\nu N_0 V/d$ amp./m.², where N_0 is the space-charge electron density in the insulator at the surface in contact with the cathode, and the approximate transition voltage between space-charge limited and proportional currents should be given by $V_S = 8ed^2N_0/9\varepsilon$ volts. These calculations have been extended by Lampert[2] to include the effects of deep trapping states. His equations show that as the applied voltage is increased the current flow should initially be very small, but should rise extremely rapidly at a certain critical voltage to reach the space-charge limited value at an applied voltage given approximately by $V_t = ed^2N_t/2\varepsilon$ volts, where N_t is the density of trapping states. A further case of interest has been studied by Skinner[3], who has considered the flow of current in an ideal insulator bounded by two metal electrodes of different work functions. These calculations indicate, as expected, that current rectification should be obtained.

These anticipated properties of space-charge limited currents in insulating materials suggest the exploitation of these currents to develop a new class of solid state devices[4]. Experiments to this end have been made in my laboratories during the past two years and the expected characteristics of these currents have been demonstrated in crystals of cadmium sulphide.

Fig. 1 shows the steady current – voltage characteristic of a thin crystal plate about 3 × 10^{-3} cm. thick. The crystal was provided with a cathode of indium metal about 1 mm.² in area, vacuum-welded to one surface, and an anode, in the form of a coating of colloidal graphite, on the other surface. The curve

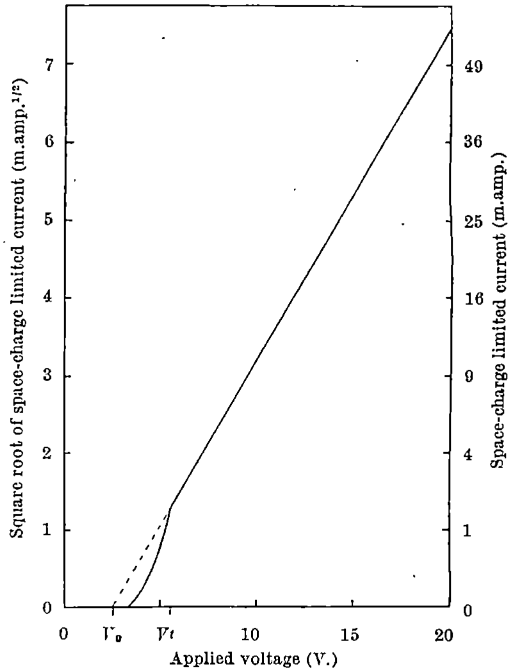

Fig. 1. Current – voltage characteristic of space-charge limited current in a cadmium sulphide crystal. The curve shows the relation between the square root of the current and the applied voltage

shows the forward current characteristic for this crystal measured at room temperature (20° C.) and is typical of the results obtained so far. Photoconductive effects were eliminated by enclosing the crystal in a light-tight container. As the applied voltage was raised no current-flow could be detected ($i < 0{\cdot}05$ μamp.) until a voltage $V_0 = 2{\cdot}5$ volts was reached. The presence of this threshold voltage is attributed basically to the difference in magnitude between the electron affinity of the crystal and the work function of the anode; this difference must be overcome by the applied voltage before appreciable current can flow. As the applied voltage was increased further a very small current commenced which then rose rapidly to about 2 m.amp. at a voltage $V_t = 5{\cdot}7$ volts. In this region considerable time was required for the current flow to reach a steady value and the current – voltage curve was quite steep up to the space-charge limited value. These characteristics are attributed to the influence of deep trapping states. This measured value of V_t indicates that the density of deep trapping states in this crystal was of the order of 10^{13} per cm.^{3}, which is satisfyingly low. For higher voltages the current flow was quite steady and reproducible provided that thermal effects due to power dissipation were avoided. In this region the precise square-law characteristic expected for space-charge limited currents was obtained. From the slope of this part of the curve the mobility of the electrons in the crystal was found to be approximately 500 cm.^{2}/V. sec. This is a rather high figure for cadmium sulphide, but is probably explained by the relative freedom of this particular crystal from lattice defects and trapping states.

In order to supply the magnitudes of space-charge limited currents observed, the electron space-charge density N_0 in the crystal at the surface in contact with the cathode must have been of the order of 10^{19}/cm.^{3}. This implies that the conduction band of the crystal at the cathode was within 0·05 eV. of the Fermi-level of the cathode metal.

In the reverse direction the crystal was, as expected, an insulator. At applied voltages up to 20 V. the current flow was undetectable with a sensitive galvanometer, indicating a reverse resistance greater than 10^{11} ohms. At 80 V. the reverse resistance was still of the order of 10^{10} ohms.

These various properties of current flow in insulators make this a worthwhile field for fundamental studies and for the design and development of new solid state devices. For example, much information can be obtained about lattice defects in dielectric crystals by studying electron trapping and scattering; the electron affinities of dielectric crystals can be measured directly, giving useful information to assist theoretical studies of crystal and surface structures; and the nature of contacts between conductors and insulators can be examined directly. From the point of view of the developing devices the exploitation of space-charge limited currents in insulating materials is attractive for many reasons apart from the promise of many new types of devices. For example, by working under space-charge limited conditions, relative insensitivity to changes in temperature should be achieved; this is an appreciable advantage for a solid state device.

As yet only preliminary experiments and measurements have been made and it is certain that many problems have to be solved before successful and reliable devices can be designed. Even so it seems clear that the study of space-charge limited current flow in insulating materials will be a fruitful field for fundamental investigations and will lead to the development of many new types of solid state devices.

I wish to thank Prof. D. G. Tucker for the provision of facilities for this work and the National Research Development Corporation for its interest and financial support.

Effects of Electron Bombardment upon Sodium Tetraborate and Boric Acid in an Electron Microscope

THE specimens under observation in the electron microscope are exposed simultaneously to a high vacuum and to electron bombardment. Under these conditions, the specimens may lose volatile constituents due to the combined effects of the vacuum and of the temperature rise[1,2]; also the crystal structure may undergo alterations as a result of exposure to the electron beam[3].

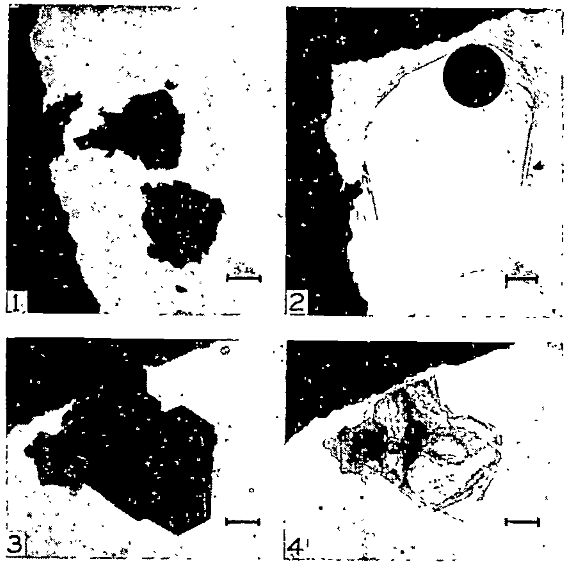
A systematic study was conducted on the effect of electron bombardment upon crystals in an electron microscope, especially on acetates, carbonates, oxalates and some crystalline organic acids (Souza Santos, H. L., unpublished work). This study was intended to correlate the morphological changes in the crystal which are observable with the electron microscope and the physical and chemical transformations with the temperature rise which can be expected from the chemical composition of these substances.

In the course of these studies, some observations on the behaviour of sodium tetraborate and boric acid were made which are of interest in view of the similarity of the effects of temperature of these substances[4].

Sodium tetraborate dissolves in its own water of crystallization at 75° C. at atmospheric pressure; it loses five molecules of water at 100° C. and nine at 150° C., becoming anhydrous and melting at 320° C. On further heating, it swells up to a spongy mass; at a higher temperature, this mass runs together, forming a clear colourless glass—borax glass—the melting point of which is reported[5] to be between 561° and 878° C.

Boric acid, when heated to 70° C., loses no water; at 100° C., it loses two-thirds of its water and at 160° C. it melts, forming dihydrotetraboric acid ($H_2B_4O_7$). At a higher temperature, the acid froths up, losing its water and forming a fused viscid mass of anhydride, which on cooling congeals to a transparent but fissured glass. At a red heat, boric acid loses all its water with much bubbling[4].

From their physico-chemical properties, it could be predicted that sodium tetraborate and boric acid would give similar effects under electron bombardment, namely, melting of the crystals, formation of spherical drops or reunion of many drops into a single one, loss of water as vapour accompanied by bubbling, residues of borate glass and boric anhydride.



Figs. 1 and 2. Sodium tetraborate crystals before and after bombardment

Figs. 3 and 4. Boric acid crystals before and after bombardment Scale: 5μ

The following method was used for preparing the specimen. Dry powdered samples of analytical grade boric acid (H_3BO_3) and sodium tetraborate ($Na_2B_4O_7.10H_2O$), were deposited on nickel grids covered with 'Parlodion'; the excess solid was removed by turning the grids upside down, thus leaving some minute crystals adhering to the plastic. An *RCA* type *EMU* electron microscope operating at 50 kV. with self-biased gun was used. The lowest possible current intensity was used at first, and this was raised until the morphological changes appeared. Wherever possible, electron micrographs were taken at the initial, intermediate and final stages of bombardment.

Under electron bombardment the particles of sodium tetraborate seem to melt, giving spherical drops; when many particles are in contact the drops aglomerate into a single drop, as do liquid drops, due to surface tension. Fig. 1 shows sodium tetraborate particles taken with a low-intensity electron beam. Fig. 2 shows the same particles after strong bombardment; the particles are united into one almost spherical particle.

In the electron microscope electronically dense particles of boric acid lose their opacity to electrons, leaving transparent envelopes, which retain the original shape of the particles. Fig. 3 shows some boric acid crystals in an early stage of bombardment; a region is becoming transparent; before bombardment the whole crystal was quite opaque. In Fig. 4 the same crystal shows only the residual transparent envelope after strong bombardment.

The predictions were confirmed in the case of sodium tetraborate, but not for boric acid, the behaviour of which is that of a completely volatile material; this contradiction could be explained by the fact that boric acid is relatively volatile in steam[1, 6]; its vapour pressure is 242 mm. of mercury at 128° C., this temperature being in the range of calculated values for specimens in an electron microscope[7].

Further studies are in course and will be published elsewhere.

Origin of Tektites

In the recent controversy concerning the origin of tektites[1,2], Kopal has given reasons for considering that they must be formed close to the terrestrial surface, and regards these as grounds for favouring Urey's cometary theory[3]. It appears useful to direct attention to another suggestion which may have been overlooked—the 'plastic sweeping' theory of Hardcastle[4].

Briefly, Hardcastle suggests that tektites have been formed from stony meteorites by the process of ablation during their passage through the atmosphere. The glazed surface of these meteorites is considered to contain an enriched content of silica, and to be swept away piecemeal during flight. The solidified remnants land as tektites. The considerable ablation known to take place, and the comparatively long-lived trails observed in stony meteorite falls are adduced to support the theory. Attention is also directed to the marked pitting of the stones and the size of the pits.

An analysis of the glazed surface material would enable a test of this suggestion to be made. It might be expected to contain a selective sample of the material of the meteorite rather than to reflect the average composition. In view of Urey's statement that "the chemistry of silicate material is not completely known", such an analysis would provide additional relevant data.

The 'plastic sweeping' theory appears to explain: (1) the derivation of tektite material from meteorites of known composition; (2) a rapid heating process capable of producing the observed physical forms; (3) an explanation of the wide scattering. The most serious objection appears to be the limited time-scale within which tektite falls are known to have taken place. Urey, on the other hand, appears to consider two comets only, one in Eocene time, which produced the bediasites, and the other in the Pleistocene, producing the other falls. Even granting the possibility of fragmentation of the cometary nucleus, it seems doubtful whether the observed distribution is satisfactorily explained. In these respects, the lunar impactite theory is superior.

Determination of Hammett Sigma Constants by Intramolecular Hydrogen Bonding

THE extensive literature that exists concerning Hammett's σ-constants has been subjected to several recent reviews, including a compilation and examination of available data[1], a discussion of the significance and limitations of the concepts involved[2], and an attempt to deduce best values and probable errors for the σ-values[3]. In most cases σ-values have been determined by examination of equilibrium constants or reaction-rate constants of substituted benzene derivatives, thus requiring consideration of product states or transition states. In the few instances where examination of the native (unreacted) molecule has led to a determination of σ (via physical measurements), the site examined has invariably been attached directly to the ring carrying the groups under study, thereby still exerting some influence (other than electronic) on the effect measured as well as excluding the *ortho*-position for steric reasons.

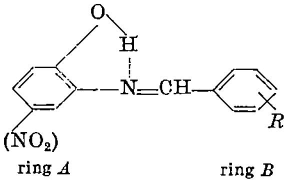
Table 1

Substituent (ring *B*)	σ-*ortho*	σ-*meta*	σ-*para*
F	+ 0·17 (*a*)	+ 0·31 (*a*) + 0·337	+ 0·15 (*a*) + 0·062
Cl	+ 0·22 (*a*)	+ 0·38 (*a*) + 0·373	+ 0·20 (*a*) + 0·17 (*b*) + 0·227
Br			+ 0·25 (*a*) + 0·24 (*b*) + 0·232
CH_3	− 0·14 (*a*)	− 0·07 (*a*) − 0·069	− 0·14 (*a*) − 0·170
NO_2		+ 0·75 (*a*) + 0·710	+ 0·778
OH	*	+ 0·05 (*a*) + 0·121	− 0·32 (*a*) − 0·37
OCH_3	− 0·34 (*a*)	+ 0·04 (*a*) + 0·11	− 0·28 (*a*) − 0·27 (*b*) − 0·268
$N(CH_3)_2$			− 0·80 (*a*) − 0·91 (*b*) − 0·83

Values (*a*) obtained with ring *A* unsubstituted, with carbon tetrachloride as solvent ($K = 0·033$). Values (*b*) obtained with a 4-NO_2-group in ring *A*, with methylchloride as solvent ($K = 0·033$). Unmarked values are from ref. 3 for comparison.

* Unobtainable due to the preferred hydrogen bonding from the ring *B* phenolic hydroxy group.

A method has been devised which permits estimation of the Hammett σ-constant in a manner circumventing many of these objections. In the system:



the group being investigated (*R*) is physically isolated from the O—H · · · N hydrogen bond regardless of its position on ring *B*. Its effect on the basicity of the nitrogen may be measured, none the less, by the strength of the hydrogen bond on the phenol group of ring *A* as determined by the exact frequency of the O—H stretching vibration. Table 1 shows various σ-constants obtained from the expression:

$$\sigma = \Delta\nu_{OH} \cdot K$$

where $\Delta\nu_{OH}$ is the frequency shift of the substituted homologue (in wave-numbers) compared with the unsubstituted parent compound, and *K* is a factor employed to bring these wave-number shifts into the range of the classic Hammett σ-values.

The figures above show that when steric effects are eliminated, the *ortho* and *para* σ-constants are nearly the same. A more elaborate discussion of the principles involved, and a description of experimental detail, will be published elsewhere.

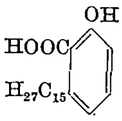
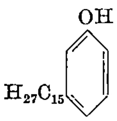
Surface-active Characteristics of Sodium Anacardate isolated from Cashew Nut Shell Oil

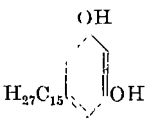
CASHEW nut (*Anacardium occidentale* Linn.) shell liquid obtained from unroasted shells was found by Stadeler[1] to consist chiefly of anacardic acid (*A*) (on heating, this is decarboxylated to cardanol (*B*)), a salicylic acid derivative with a long unsaturated side-chain in the position *ortho* to the carboxyl group, and cardol (*C*), a resorcinol derivative with a similar side-chain. Smith[2] showed that the unbranched side-chain consisted of 15 carbon atoms and 2 double bonds: other workers[3] have shown that the oily liquid is really a mixture of saturated and mono-, di-, and tri-olefinic compounds in proportions that give, on average, about two double bonds per molecule. Although the surface-active properties of the sulphonated shell liquid have already been studied[4], no thorough investigation has yet been carried out on anacardic acid, which, being an arylalkyl surfactant and a promising bactericidal agent, needs special attention[5]. Results of a preliminary study on sodium anacardate as a surfactant and bactericidal agent are reported here.



(*A*)



(*B*)



(*C*)

Shell liquid extracted with 95 per cent ethyl alcohol was saponified and the non-saponifiable material was removed by extraction with ethyl ether. Stage-wise liberation of cardol and then of anacardic acid (followed by separate extractions with ethyl ether), was carried out by passing carbon dioxide and treating the solution with dilute hydrochloric acid respectively. Dark brown anacardic acid, obtained after evaporation of the ether, and purified by charcoal treatment, had the following characteristics: specific gravity (30° C.), 1·0001; refractive index (40° C.), 1·5205; iodine value (Wij, 30 min.) 177·0 (this includes halogen substitution in the aromatic ring); iodine value determined by the corrected method of Kale and Kamath[6], 124·4. On the basis of the average molecular weight of anacardic

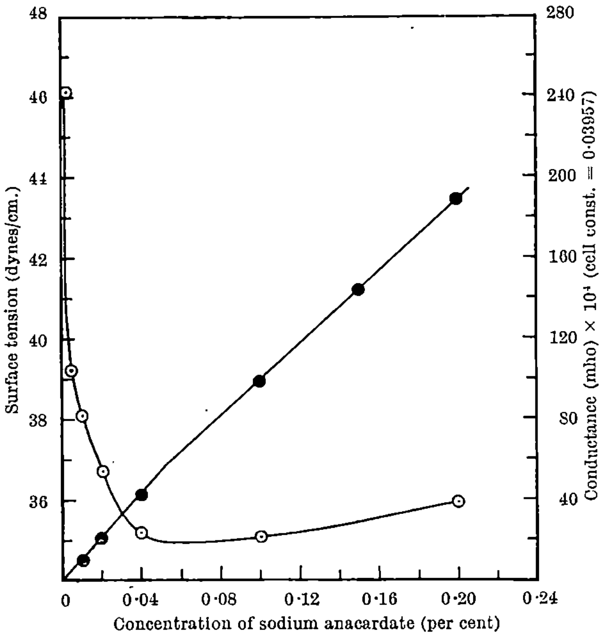


Fig. 1. ⊙, Surface tension ; ●, conductance

acid being 344, this gives an average of 1·686 double bonds per molecule.

On hydrogenation in the presence of a platinum catalyst a 95 per cent yield of white tetrahydroanacardic acid (m.p. 91·0° C.) was obtained. An alcoholic solution of anacardic acid was neutralized with slightly less than the requisite amount of alcoholic sodium hydroxide. After evaporation of most of the alcohol, the thick solution was poured into dry acetone, when the disodium salt precipitated out; this was filtered off, washed with dry acetone and dried *in vacuo*. The various surface-active properties of sodium anacardate were as follows :

(*a*) Surface tension at 25° C. (determined by Du Nuoy's tensiometer) of a 0·1 per cent solution was 35·1 dynes/cm. The surface tension/concentration curve showed a minimum in the concentration range 0·02–0·1 per cent (Fig. 1).

(*b*) The conductances of solutions of varying concentration were determined at 25° C. using a conductance meter unit, model No. 263941, Leeds and Northrup Co. The break of the specific conductance concentration curve at 0·053 per cent (Fig. 1) corresponds to the value of critical micellar concentration.

(*c*) While the interfacial tension of water against *n*-heptane was 51·24 dynes/cm. at 25° C. (Du Nuoy's tensiometer), 0·01, 0·02, 0·05 and 0·10 per cent sodium anacardate in aqueous solution lowered the value to 30·47, 20·07, 8·88 and 4·49 dynes/cm. respectively.

(*d*) 15 ml. of a 0·1 per cent solution when shaken with a 5 ml. *n*-heptane in a 25 ml. stoppered measuring cylinder (height 13 cm. and internal diameter 1·75 cm.) for 1 hr. in a shaker which had an amplitude of vibration of 11 cm. and imparted on the average 110 to-and-fro motions per minute. This emulsified the hydrocarbon almost completely. The volumes of aqueous and emulsion layers after intervals of 5 min. and 3 hr. were 13·8 ml., 5·8 ml. and 14·50 ml. and 5·10 ml. respectively. Average surface areas per unit volume of oil droplets, in 150 min.- and 24 hr.-old emulsion samples, calculated from the size distribution of the oil droplets[7], were $2·839 \times 10^3$ cm.^{2}/c.c. and $2·005 \times 10^3$ cm.^{2}/c.c. respectively. The figures denote excellent emulsion stability.

(*e*) When 200 ml. of a 0·1 per cent solution were discharged from a pipette (internal diameter of nozzle 1 mm.) on to a cushion of 50 ml. solution of the same concentration placed at the bottom of a long cylinder (internal diameter 45 mm.), the average height of fall being 75 cm., the foam heights at 0 min. and 30 min. were 16·8 cm. and 15·1 cm. respectively.

(*f*) Phenol coefficients of sodium anacardate with reference to *B. typhosa* and *S. aureus* were found to be 1·07 and 4·00 respectively. The concentrations of sodium anacardate solutions needed to kill the micro-organisms were of the same order, the large difference in the two values being due to the relatively weak influence of phenol on *S. aureus*.

These observations, coupled with the fact that sodium anacardate does not irritate the skin, indicate its suitability as a bactericidal surfactant. The inferior surface-active properties of sodium tetrahydroanacardate suggest that the ethylenic bonds were largely responsible for the greater solubility in water and the superior surface-active properties of sodium anacardate. The details of the investigations will be reported elsewhere.

We are deeply indebted to Sri Bijoy Dutta, for his co-operation in the bacteriological experiment and to Sri B. K. Mukherji of this Department for his kind interest in the work.

Kinetic Isotope Effect in the Iodination of Aromatic Amines

We have determined the kinetic isotope effect in the iodination of many aromatic amines, amino-carbonic and aminosulphonic acids by comparing the iodination-rates of normal and deutero-compounds. The results are collected in Table 1, the isotope effect being the ratio of iodination-rate constants, k_H and k_D, of normal and deuterated compounds without any correction for percentage of substitution of H by D). Relative activity, A_r, is the ratio of the rate constant of the given compound to that of iodination of *m*-dimethylaminobenzenesulphonate ion taken as 1.

Table 1 shows that *m*- and *p*-dimethylaminobenzenesulphonates are iodinated without any isotope effect ($k_H/k_D = 1$). 2,4,6-trideutero-*m*-aminobenzoate ion is iodinated slightly more slowly than the light compound. The iodination of other amino compounds is connected with a considerable isotope effect.

Similar isotope effects are observed in other cases of electrophilic substitution in aromatic compounds[1–3].

Table 1

Substance M	Substitution of H by D (per cent)	k_H/k_D	Relative activity, A_r	Experimental conditions: initial molar concentrations, *p*H, temperature (deg. C.)
2,4,6-Trideutero-*m*-dimethylaminobenzenesulphonate ion	90	1	1	M 0·076; I_2 0·008; KI 0·04; 25°
4-Deutero-1-dimethylaminobenzene-3-sulphonate ion	61	1	1	M 0·0145; I_2 0·0072; KI 0·073; phosphate 0·064; *p*H 7·0; 25°
2,6-Dideutero-1-dimethylaminobenzene-4-sulphonate ion	90	1	0·2	M 0·027; I_2 0·005; KI 0·01; 25°
2,4,6-Trideutero-*m*-dimethylaminobenzoate ion	95	1·4	35	M 0·02; I_2 0·005; KI 0·4; 30°

* This value of k_H/k_D is probably much smaller than the real one, because the percentage of substitution in the preparation used was not high

In a discussion of these results it is necessary to take into consideration the form of the general kinetic equation of iodination of aromatic amines[4], namely:

$$-\frac{d(I)}{dt} = k[M]^2[X] + k'[M][X][B] \qquad (1)$$

where M is an aromatic amine, X iodine cation or molecular iodine and B a basic component of the added buffer salt.

Equation (1) suggests that the activated complex of the reaction contains a base in the form of B or the second molecule M. One may suppose that the base acts as a proton acceptor in substitution in the benzene nucleus. However, the absence of isotope effect in iodination of dimethylaminobenzenesulphonate ions rules out this mechanism, at least in this case, because this assumption requires the proton elimination reaction as rate-determining step.

The alternative is that iodinating agents act in the form of complexes with bases $X \cdots M$ or $X \cdots B$, but that the hydrogen-splitting step does not limit the reaction-rate.

One could explain the isotope effect in iodination of other amines by supposing that bases act in these cases as proton acceptors; but considering the very great similarity of kinetic relations in iodination of various amines, we think that in all cases of iodination the base reacts in the form of a complex with I^+ or I_2. This assumption is supported by the consideration that the concentrations of (hydrated) iodine cation in the presence of potassium iodide are extremely small. Using Bell and Gelles data[5], it is easy to calculate that the iodine cation concentration in our experiments was as low as 10^{-14}–10^{-15} M. These concentrations cannot account for the observed rates of iodination of the most active amines.

At present, we cannot explain positively the established differences in k_H/k_D values in the iodination of aromatic amines. Table 1 shows that there is no connexion between the isotope effect and the iodination-rate. Indeed, the cases of presence or absence of isotope effect belong equally to high and to low values of A_r.

Grovenstein and Kilby[2] think that isotope effect in aromatic substitution is connected with the formation of stable intermediates having quinonoid structure, for example, O =  in the iodination of phenol, but the discovery of the isotope effect in the iodination of tertiary amines leads to the conclusion that the positively charged complexes $R_2\overset{+}{N}$ =  can also lose a proton as the rate-determining step.

However, the structural possibility of the formation of such intermediates is insufficient for the appearance of an isotope effect because, as we have seen, the introduction of a sulphonic group into the molecule of a tertiary aromatic amine results in disappearance of this effect. Apparently one must take into account the energetic pecularities of a reacting aromatic molecule.

Crystalline Sodium Hyaluronate

Most hyaluronates in living tissues are in the form of protein complexes. Physical-chemical investigations on these complexes yield results which differ, depending on the source of the material and also on the extent to which the hyaluronic acid was purified of proteins[1]. It appears necessary that, in addition to the descriptions of the divergences of these complexes, one should investigate the nature of the complexing itself. Two views are prevalent in this matter. Noguchi[2] advocates a pure electrostatic interaction between protein and polyuronide, and Partridge[3] believes that the polyuronides have an orienting effect on proteins upon complexing. The last view presupposes certain stereospecific interactions besides electrostatic forces. Although hyaluronates are known to be birefringent and electron-microscopic investigations indicate a fibril structure[4], X-ray diffraction studies have so far proved that hyaluronic acid films or fibres are of amorphous nature.

Sodium hyaluronate was isolated from umbilical cords by a combination of processes (pepsin and trypsin digestion, Sevag process, extraction of sulphated polyuronides with ammonium sulphate and pyridine, final removal of protein by Lloyd's reagent). The resulting material was homogeneous

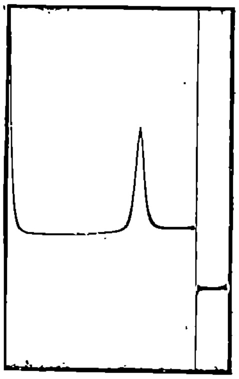

Fig. 1. Sedimentation pattern of sodium hyaluronate in 1 per cent aqueous sodium chloride solution

as observed in ultracentrifuge (Fig. 1), and had a weight-average molecular weight of 70,000. This low molecular weight, as compared to 1–4 million obtained by other authors[5] indicates that the complete removal of proteins from the preparation is achieved only at the expense of the hyaluronate chain. Although glucuronic acid and sodium were present in the preparation close to the theoretical amounts, both micro-Kjeldahl nitrogen and photocolorimetric analysis of N-acetyl glucosamine indicated that beside depolymerization a loss of nitrogen might have occurred to the extent of at least 10 per cent. However, the preparation was free from proteins and from sulphate-containing polyuronides.

Sodium hyaluronate dried from ethanol precipitation and humidified to 10 per cent moisture content yielded a highly crystalline powder diagram with as many as 22 observable reflexions (Fig. 2). The two different exposure times on the photograph were employed to show the higher order of reflexions. Detailed crystallographic analysis of the structure of sodium hyaluronate will be published shortly.

The fact that sodium hyaluronate containing approximately 3 per cent of protein (sample from the last purification step) yields an amorphous X-ray diagram indicates that the protein is strongly bound to the polyuronides, being attached at frequent spacings, and therefore, it disrupts the three-dimensional lattice array even if it is present in small quantities.

Changes in Ultra-Violet Absorption Spectra of Deoxyribonucleic Acid by Treatment with Bromine

IN 1947, a procedure was developed[1] for the determination of pyrimidine nucleoside in which bromination and prolonged acid hydrolysis precede the performance of Bial reaction. More recently, it was also shown that marked changes in ultra-violet absorption spectra, particularly disappearance of selective absorption of cytosine, uracil and their nucleosides, occurred before and after the bromination of the compounds[2]. While studying the effects of bromine on the chemical nature of nucleic acids, we have also found that the maximal absorption of deoxyribonucleic acid shows a decrease with increasing bromination period. In further experiments, it has also been demonstrated that acid hydrolysis of brominated deoxyribonucleic acid results in a loss of selective absorption without significant loss of phosphorus.

White fibrous sodium deoxyribonucleate of herring sperm giving a negative biuret test was prepared[3] by deproteinization[4] from a commercial one (Minophagen Pharm. Co., Ltd., Tokyo). The preparation showing the analytical data of 8·6 per cent for phosphorus[5] and 14·9 per cent for nitrogen (Kjeldahl–Parnas) was used throughout this study. 60 ml. of 0·3 per cent sodium deoxyribonucleate solution and an equal volume of 2 per cent bromine water preincubated separately at 37° C. for 10 min. were combined in a tightly glass-stoppered flask. Immediately after mixing, the reaction mixture was incubated at 37° C. with occasional shaking. 10-ml. aliquots withdrawn at intervals were vigorously aerated for 3 min., when the solution became almost colourless. A few drops of diluted aqueous ammonia were then added to eliminate free bromine completely and to adjust *p*H at around 6. Mixtures thus treated were transferred to each 'Cellophane' bag for dialysis against running tap water (below 12° C.) for 2 days then against frequent changes of distilled water in the cold until no ammonium salt could be detected (Nesseler test) in the dialysate (about 3 days were needed). Inside liquid and washings were combined and distilled water was added to a final volume of 20 ml. 10-ml. portions of each solution were adjusted at *p*H 1·5 (glass-electrode) by dropwise addition of 2 *N* hydrochloric acid, when little or no turbidity occurred with brominated deoxyribonucleic acid whereas prompt precipitates arose with non-treated ones. After 30 hr. incubation at 37° C., solutions were placed in each 'Cello-

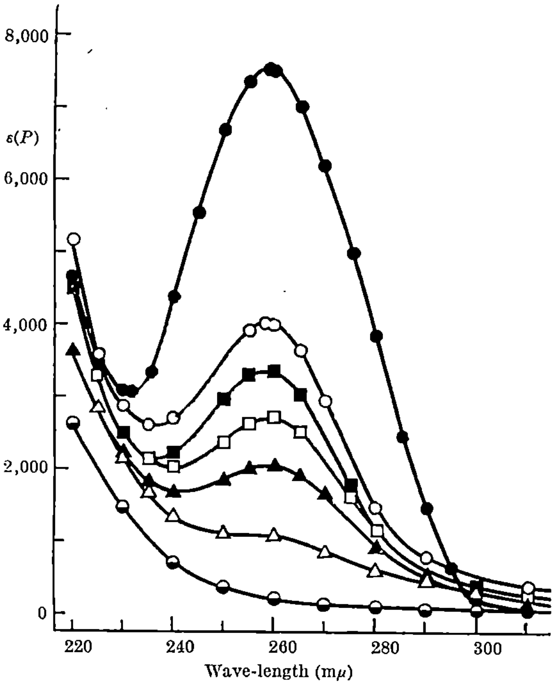

Fig. 1. Ultra-violet absorption spectra of brominated deoxyribonucleic acid in 1/15 *M* phosphate buffer of *p*H 7·0. Bromination period: 0 (original acid), —●—; 1·5 min., —○—; 3 min., —■—; 1 hr., —□—; 2 hr., —▲—; 5 hr., —△—; 12 hr., —⊖—

phane' bag to dialyse as mentioned above and the final volume was made up to 20 ml. by the addition of distilled water. Solutions thus treated were then measured for ultra-violet absorption spectra with a Beckman-type spectrophotometer, phosphorus according to Fiske and Subbarow[6] and nitrogen by the method of Kjeldahl–Nesseler[7].

From Fig. 1, showing typical changes in absorption spectra resulting from the bromination of deoxyribonucleic acid, no major shift will be seen in the absorption maxima so long as the acid was treated for a short time; however, ε(*P*) decreased with the increase of time to a complete loss of the selective absorption. Furthermore, as depicted in Fig. 2, the remaining absorption of brominated deoxyribonucleic acid was completely removed by the treatment with hydrochloric acid. Since the brominated acid was hydrolysed under the same conditions as employed for the preparation of apurinic acid and compounds, the spectra of which are given in Fig. 2, and had a nitrogen content similar to that of apurinic acid (N : P = 0·55)[3], it may be concluded that the pyrimidine moiety in brominated deoxyribonucleic acid was not liberated upon hydrolysis under the conditions employed and hence, extinction of brominated deoxyribonucleic acid was contributed by the purine moiety. On the other hand, diminution of nitrogen content was accompanied by the abatement of extinction with increasing bromination period. However, short bromination lessened markedly the absorption without significant loss of nitrogen. Decrease in quantity of nitrogen may be caused by the acidity of bromine water as a result of the liberation of purine bases. In all cases, the recovery of phosphorus was almost quantitative (more than 90 per cent) and the colour yield of the reaction of brominated deoxyribonucleic acid with diphenylamine[8] did not decrease within 20-min. bromination when comparison was made on the basis of phosphorus content.

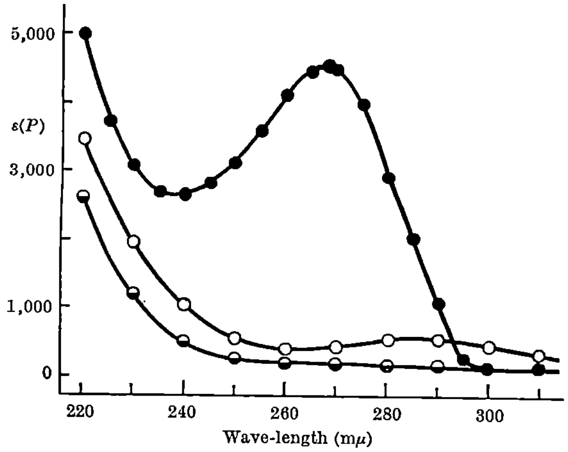

Fig. 2. Ultra-violet absorption spectra of brominated deoxyribonucleic acid hydrolysed with hydrochloric acid (in 1/15 *M* phosphate buffer of *p*H 7·0). Bromination period; 0 (apurinic acid), —●—; 1·5 min., —○—; 12 hr., —⊖—

Although the mode of action of bromine on deoxyribonucleic acid still remains uncertain, these results clearly indicate that bromine exerts a distinct influence particularly on the ultra-violet absorption spectra, and deoxyribonucleic acid gives a derivative devoid of any absorption characteristics of nucleic acids by a short bromination followed by mild acid hydrolysis.

Yeast ribonucleic acid showed rather different behaviour from deoxyribonucleic acid towards bromine treatment. Further work is now in progress and details will be published elsewhere.

Preparation of Kojibiose

PREVIOUSLY, we detected kojibiose (2-O-α-D-glucopyranosyl-D-glucopyranose) in *sake* and its *moromi* and isolated it from a mixture of oligosaccharides synthesized from maltose and glucose by the culture filtrates of *Aspergillus oryzae*[1], *Asp. niger*[2] and *Schizosaccharomyces pombe*[3]. It was also isolated from hydrol[4]. Sato and Aso[5] crystallized it as α- and β-octaacetates, and Matsuda[6] and Haq and Whelan[7] synthesized it chemically.

The proportion of kojibiose in the sources was very small. Moreover, the separation of kojibiose from other disaccharides, especially *iso*maltose, by preliminary carbon column chromatography, was very difficult, as was its synthesis.

This communication deals with the preparation of kojibiose. Previously, it was reported[8] that when the dextran-producing organism *Leuconostoc mesenteroides* is grown on a medium containing sucrose, in the presence of large amounts of 1,4-α-linked glucose polymers, 1,6-α-linked oligosaccharides are produced in appreciable quantities. A particularly interesting example was that of Bailey *et al.*[9], who isolated, by charcoal chromatography, a new trisaccharide from a culture of *Betacoccus arabinosaceous* (Birmingham strain), which had been grown on a medium containing yeast extract, inorganic salts, sucrose and lactose. They determined its structure as O-β-D-galactopyranosyl-(1 → 4)-O-[α-D-glucopyranosyl-(1→2)]-D-glucopyranose. They reported that cleavage of the β-linkage in the trisaccharide by almond β-glycosidase was extremely slow, and that some 50 per cent of the trisaccharide remained after three weeks. They did not isolate kojibiose in a crystalline form.

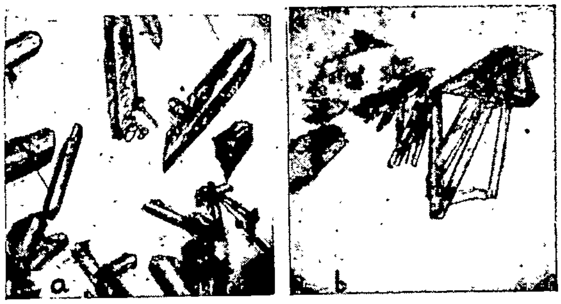

Fig. 1. *a*, α-Kojibiose octaacetate ; *b*, β-kojibiose octaacetate

Considering the structure, if the 1,4-β-linkage (lactose) in the trisaccharide is cleaved by *Saccharomyces fragilis* lactase, kojibiose and galactose will be easily obtained. By this method we obtained kojibiose in almost theoretical yield.

A culture of *Leuconostoc mesenteroides* (dextran-producer) instead of *Betacoccus arabinosaceous* (Birmingham strain) was prepared in a medium containing the following ingredients per l.; sucrose 30 gm., lactose 100 gm., ammonium sulphate 0·6 gm., potassium phosphate 5 gm., sodium chloride 1 gm., magnesium sulphate 0·2 gm. and yeast extract 1 gm. The inoculated medium was incubated for 10 days at 27–28° C. The formation of the trisaccharide was detected by paper chromatography and it was isolated by carbon-column chromatography. The yield was 46 gm. from the culture medium (10 l.).

0·5 gm. of the lactase preparation of *Saccharomyces fragilis*[10] (kindly supplied by Dr. Henry Roberts) and 10 gm. of the trisaccharide were added to 100 ml. of 0·067 *M* phosphate buffer, *p*H 6·2. This solution was incubated at 35° C. for 30 hr. Galactose, kojibiose, a trace of glucose and the trisaccharide were detected by paper chromatography. 5 gm. of kojibiose were isolated by carbon-column chromatography. By acetylation with acetic anhydride and sodium acetate, crystals of the α- and β-octaacetates of kojibiose were obtained. The α-form had m.p. 166° C. (yield 1·7 gm.); the β-form had m.p. 117–118° C. (yield 3·5 gm.). Further, by acetolysis of 10 gm. of the trisaccharide with acetic anhydride (50 ml.), glacial acetic acid (32 ml.) and concentrated sulphuric acid (6 ml.) at room temperature for 7 days, 0·4 gm. of α- and 0·8 gm. of β-kojibiose octaacetates were obtained in crystalline form.

Origin of the Methoxyl Groups in Spirilloxanthin—a Carotenoid synthesized by the Photosynthetic Bacterium *Rhodospirillum rubrum*

It can now be stated with a reasonable assurance that the repeating (isoprene) unit of all terpenoid compounds arises from two-carbon (acetate) units via mevalonic acid (β,δ-dihydroxy-β-methylvaleric acid) or a closely related compound[1]. Occasionally, however, additional carbon atoms appear the origin of which cannot readily be referred to an isoprene unit; this is most marked in the plant sterols and perhaps the best example is ergosterol with its additional methyl substituent at C_{24}. It has been shown that this group arises by means of the transfer of a one-carbon unit from a donor such as active methionine or formyl- or hydroxymethyl-tetrahydrofolic acid, because formate-^{14}C is readily and specifically incorporated into C_{28} of ergosterol in yeast[2].

The only carotenoids which are known to contain such 'supernumerary' groups are those predominating in the photosynthetic bacteria. These have methoxyl groups attached to either positions 3 and 3′ or 4 and 4′; the best known pigment of this type is spirilloxanthin[3] (Fig. 1), which represents more than 95 per cent of the total carotenoids in mature cultures of *Rhodospirillum rubrum*[4]. Experiments have now been carried out which demonstrate that the methoxyl carbons of spirilloxanthin arise from a one-carbon unit and not from a degraded two-carbon unit.

Young anaerobic cultures of *R. rubrum* contain a mixture of carotenoids, the major components being lycopene, lycoxanthin (3-hydroxylycopene), *P*-481 and hydroxy *P*-481 (pigments of undecided structure but which must be intermediate between lycopene and spirilloxanthin) and spirilloxanthin[4]. If such

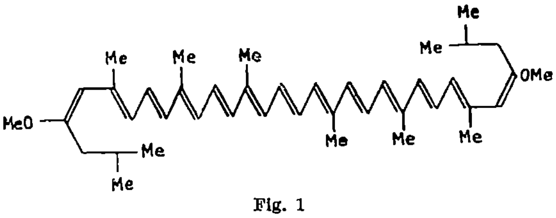

Fig. 1

cultures are washed and resuspended anaerobically in phosphate buffer, additional spirilloxanthin is synthesized while the remaining pigments disappear; the amount of spirilloxanthin formed is stoicheiometrically equivalent to the amount of the other pigments disappearing[5]. These observations strongly suggest that lycopene is converted into spirilloxanthin via *P*-481, etc., as intermediates. If direct methylation occurs during this transformation then addition of a labelled one-carbon compound to washed young cells should yield spirilloxanthin labelled only in the methoxyl groups. Consequently, 36-hr. anaerobic cultures grown under our standard conditions[6] were washed and resuspended anaerobically in the light in *M*/15 phosphate buffer (*p*H 7·0) to which had been added formate-^{14}C. 24 hr. later the cells were harvested, the spirilloxanthin extracted, purified chromatographically[6] and diluted with unlabelled crystalline spirilloxanthin isolated previously from large-scale cultures of *R. rubrum*. The pigment was then recrystallized from benzene to constant specific activity and the methoxyl groups oxidized to methyl iodide using standard micro procedures; the methyl iodide was trapped in freshly distilled quinoline[7]. Approximately 51 per cent of the total activity in the spirilloxanthin was found to be located in the trapped methyl iodide. Allowing for possible losses in the degradation of the pigment and in trapping the methyl iodide, this result leaves no doubt that formate is specifically incorporated into the methoxyl carbons of spirilloxanthin; a random distribution would have yielded less than 5 per cent of the total counts in the methoxyl carbons. Furthermore, the adequacy of the degradation from the isotope point of view was demonstrated by degrading a highly active sample of β-carotene, a carotenoid which contains no methoxyl groups; only 0·16 per cent of the added label was recovered in the quinoline-trapping agent.

Although it has not been possible to demonstrate directly that it is a methyl group rather than a methoxyl group which is transferred, the first possibility is much more likely because (*a*) transmethylation is a well-known and widespread biochemical reaction while transmethoxylation has not yet been reported and (*b*) probable hydroxylated methyl acceptors such as lycoxanthin, hydroxy *P*-481 and 'demethylated' spirilloxanthin[6,8] are present in young *R. rubrum*.

The occurrence of O-methylation in the carotenoids also fits in with the work of Birch *et al.*[9], who found that the methoxyl (and methyl) groups of the benzene ring of mycophenolic acid produced by *Penicillium brevi-compactum* arise similarly by one-carbon transfer, in this particular case from the S-methyl group of methionine.

Only about 25 per cent of the total formate incorporated into the unsaponifiable matter of *R. rubrum* is present in spirilloxanthin. Apart from the carotenoids, the nature of the other unsaponifiable components of *R. rubrum* is unknown but sterols do not appear to be present. It is interesting that formate is rapidly incorporated into this unknown fraction.

A question which still remains to be answered is, why the photosynthetic bacteria methylate their xanthophylls. Xanthophylls are abundant in all other photosynthetic organisms (higher plants and algae) but there is no indication that they are ever methylated[10].

We wish to thank Prof. A. J. Birch for a generous gift of formate-^{14}C and Dr. W. B. Whalley for arranging for the methoxyl determinations to be carried out in the Department of Organic Chemistry of the University of Liverpool.

Electrophoresis of Fluorescent Antibody

A COMPLICATION often encountered in the use of the fluorescent antibody technique of Coons and Kaplan[1] is the presence of non-specific staining material in the conjugates, even after exhaustive dialysis. Apart from its nuisance-value, the effect is of interest because it does not occur when fluorescein-globulin reacts with sections of various malignant tissues[2,3].

A number of methods have been suggested for diminishing non-specific staining. Coons and Kaplan[1] used absorption with acetone-dried powders of certain tissues. It has also been found possible to isolate specifically staining fluorescent antibody by absorption to and elution from columns of antigen coupled powdered cellulose (unpublished work). These methods are of uncertain reproducibility, working well with some antibodies and tissues, but not with others. This communication presents some preliminary results of a physico-chemical study on fluorescein-protein conjugates, made in the hope of gaining more information about the chemistry of non-specific staining.

The electrophoresis pattern (Fig. 1) of fluorescein-conjugated human γ_2-globulin (8 μgm. fluorescein/mgm. of protein) shows marked heterogeneity. The spike has a mobility of $-1·46 \times 10^{-5}$ sec.$^{-1}$ V.$^{-1}$ cm.^{2} in sodium diethylbarbiturate buffer (*p*H 8·6, *I*, 0·1). A tracing of the ascending boundary of this pattern is superimposed in Fig. 2 on that of normal γ_2-globulin (mobility, $-1·01 \times 10^{-5}$ sec.$^{-1}$ V.$^{-1}$ cm.^{2} in sodium diethylbarbiturate buffer, *p*H 8·6, *I*, 0·1).

If the conjugate is shaken with acetone-dried rat liver powder[1] in phosphate buffer (*p*H 7·2, *I*, 0·1) a reduction in the area of the leading peak is observed (Fig. 3). If the γ_2-globulin was prepared from sera of

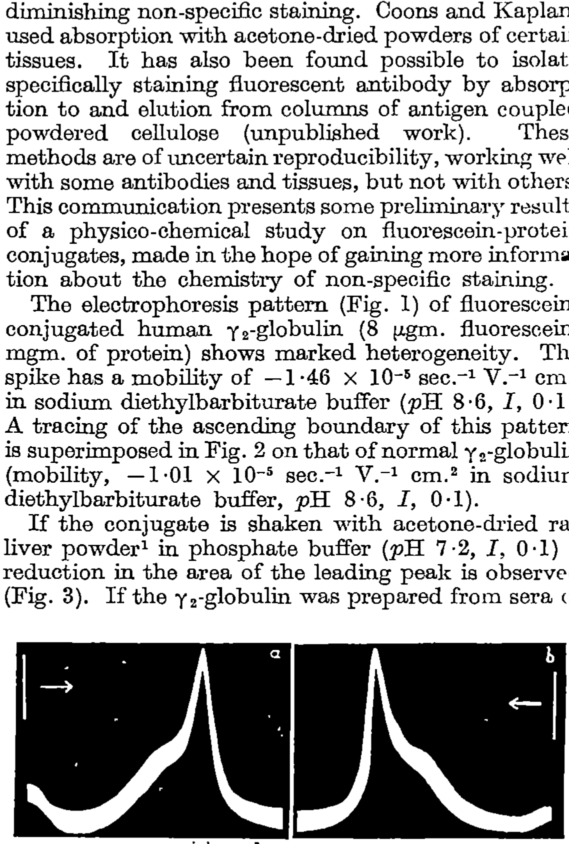

Fig. 1. Electrophoresis of fluorescein-conjugated human γ_2-globulin in sodium diethylbarbiturate buffer (*p*H 8·6, *I* 0·1). *a*, ascending, *b*, descending. The vertical line and arrow indicate origin and direction of migration in each case

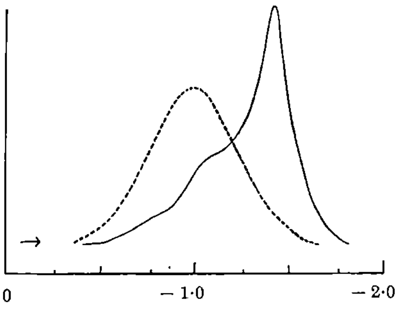

Fig. 2. Tracing of the ascending boundary of Fig. 1 superimposed on that of normal γ_2-globulin (broken line) in sodium diethylbarbiturate buffer (pH 8·6, I 0·1)

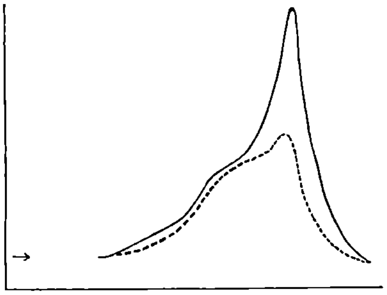

Fig. 3. The ascending electrophoresis pattern of rat liver powder-absorbed fluorescein-rabbit γ_2-globulin superimposed on that of unabsorbed fluorescein globulin (broken line). Electrophoresis in sodium diethylbarbiturate buffer (pH 8·6, I 0·1)

rabbits hyperimmunized against ovalbumin (domestic fowl) this marked diminution was associated with a loss of only 25 per cent of the antibody activity, as determined by diffusion in agar[4]. In contrast to the unabsorbed conjugates the absorbed material gave very little non-specific staining under the fluorescence microscope when applied to smears of leucocytes from normal human blood.

Attempts at separating the antibody from the non-specific staining activity by electrophoresis with starch blocks and powdered cellulose supporting media proved disappointing. An appreciable portion of the fast non-specifically staining material tailed during the run and was eluted with the antibody fraction.

However, it was possible to fractionate the fluorescein-globulin conjugate by electrophoresis convection. A 3 per cent solution of fluorescein-rabbit γ_2-globulin (containing anti-ovalbumin) was subjected to electrophoresis convection in an apparatus after the design of Raymond[5] at 20 V. cm.$^{-1}$ in six stages in phosphate buffer from pH 8·0 to 5·5 (I, 0·1), the pH being lowered by 0·5 at each stage. The assays of the top fraction from each stage are given in Table 1. It can be seen that the first two stages contain high-titre fluorescent antibody with no non-specific staining properties, and that the last fractions are the most heavily conjugated.

Table 1. ASSAY OF FLUORESCEIN-GLOBULIN FRACTIONS OBTAINED BY ELECTROPHORESIS-CONVECTION

Fraction	1 (pH 8·0)	2 (pH 7·5)	3 (pH 7·0)	4 (pH 6·5)	5 (pH 6·0)	6 (pH 5·5)	Starting material
Protein conc. (mgm./ml.)	2	4	7	7	6	5	30
Fluorescein content (μgm./ml.)	3	8	17	31	63	51	240
Antibody titre	150	430	180	150	100	60	1,024
Non-specific staining	—	—	+	++	+++	+++	+++

These findings present another facet of the well-known heterogeneity of γ-globulin—in this case its heterogeneous chemical reactivity. It is interesting to note that human serum albumin and a relatively homogeneous myeloma globulin both increased in mobility, but only slightly in heterogeneity (estimated by reversible boundary spreading) on conjugation with fluorescein *iso*cyanate.

Reconstruction of the Reaction Mechanism of Cytochrome Oxidase

PREVIOUSLY it has been generally believed that the substrates of the cytochrome oxidase system, such as p-phenylene diamine and hydroquinone, are only oxidized by cytochrome oxidase through cytochrome *c*. However, since p-phenylene diamine is fairly well oxidized by particulate cytochrome oxidase preparations in the absence of cytochrome *c*, whereas the other substrates, such as hydroquinone are not, Okunuki[1] has suggested that the reductant of the so-called Nadi-reaction can reduce not only cytochrome *c* but also cytochrome oxidase. This was confirmed spectrophotometrically by Smith[2].

Recently, we reported[3] several properties of our cytochrome *a* preparation and showed that dithionite-reduced cytochrome *a* is oxygenated rather than oxidized by oxygen in the absence of cytochrome *c*. We also showed that in the presence of a small amount of reduced or oxidized cytochrome *c* the oxygenated cytochrome *a* is rapidly oxidized. In this communication the reduction velocity of cytochrome *a* by p-phenylene diamine, hydroquinone, and ascorbic acid in a solution of a synthetic non-ionic detergent, 'Emasol' 4130[4] is reported. We also confirm the role of cytochrome *c* in the appearance of the cytochrome oxidase activity of cytochrome *a*.

Cytochrome *a* in 'Emasol' 4130 is readily reduced by the addition of 10^{-3} *M* p-phenylene diamine as measured by the change in optical density of the α-band. The velocity measured by the change in the γ-band is somewhat less, due to contamination of the oxygenated form. In contrast to the results of Smith, we find that hydroquinone and ascorbic acid can also reduce cytochrome *a*, though at a slower rate than p-phenylene diamine. In an initial 1-min. reaction and at a concentration of 10^{-3} *M* the percentage reduction of cytochrome *a*, measured by the change in its α-band, is 92 for p-phenylene diamine, 55 for hydroquinone and 39 for ascorbic acid. When measured manometrically in the absence of cytochrome *c*, none of these substrates caused any uptake of oxygen. However, addition of cytochrome *c* to the cytochrome *a* preparation causes a large oxygen uptake (Table 1).

On the other hand, when a trace of borohydride is added to decrease the concentration of oxygen in the

Table 1. Influence of Addition of Cytochrome *c* on the Cytochrome Oxidase Activity of Cytochrome *a* (Oxygen Uptake/10 min.)

System \ Substrate (10^{-2} *M*)	*p*-Phenylene diamine	Hydroquinone	Ascorbic acid
No addition	4 μl.	4 μl.	10 μl.
Cytochrome *a*	6	4	4
Cytochrome *a* + cytochrome *c* ($1\cdot4 \times 10^{-5}$ *M*)	104	126	80

cuvette, cytochrome *a* is oxygenated in aerobic conditions and reduced in anaerobic conditions by the addition of 10^{-4} *M* *p*-phenylene diamine.

When a trace of cytochrome *c* is added to either system, either form of cytochrome *a* is instantaneously oxidized (Fig. 1).

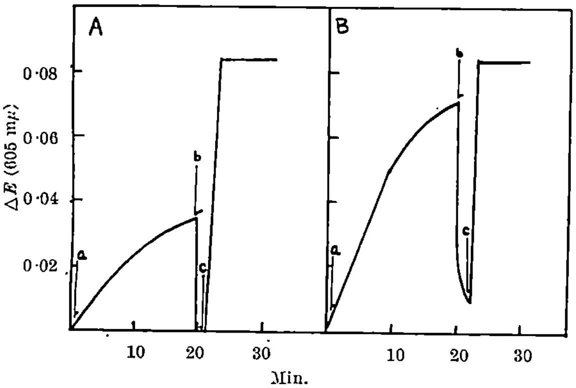

Fig. 1. Effect of cytochrome *c* on the oxidation of cytochrome *a*. Experiments conducted spectrophotometrically in a cuvette of 1 cm. light-path: *A*, cytochrome *a* incubated aerobically; *B*, anaerobically. Arrows indicate addition of each reagent: (*a*) 10^{-4} *M* *p*-phenylene diamine and trace of sodium borohydride; (*b*) 5×10^{-9} *M* of oxidized cytochrome *c*; (*c*) trace of sodium dithionite

Considering these findings in relation to those of Yakushiji and Okunuki[5] that electrons are also transferred from cytochrome *a* to cytochrome *c*, it seems that the electron in the hæm of cytochrome *a* does not participate in the cytochrome oxidase reaction unless cytochrome *c* is present in the system. The following scheme is therefore suggested to illustrate the reaction mechanism of cytochrome oxidase.

Preparation of Crystalline *Pseudomonas* Cytochrome$_{551}$ from *Pseudomonas aeruginosa*

Using a strain of *Pseudomonas aeruginosa*, we have already succeeded[1-3] in the purification of four kinds of respiratory components—*Pseudomonas* (*P*-) cytochrome oxidase containing the so-called cytochrome a_2, *P*-cytochrome$_{551}$, *P*-cytochrome$_{554}$ and *P*-blue protein—in forms soluble in water, without the aid of detergents. The crystallization of *P*-blue protein has been described[2]. Here the crystallization of *P*-cytochrome$_{551}$ is reported.

The principle used is as follows. (1) Extraction of the cytochrome from an acetone-powder of the cells. (2) Removal of viscous substances with acidic isoelectric points, such as nucleic acids, by the addition of rivanol. (3) Removal of substances with alkaline isoelectric points by treatment with 'Duolite' *CS*-101, which has similar properties to 'Amberlite' *XE*-64. (4) Rough fractionation of *P*-cytochrome$_{551}$ by chromatography on a column of specially buffered, activated aluminium oxide. (5) Fractionation by zone-electrophoresis on a column of raw potato starch. (6) Precipitation from ammonium sulphate solution, taking advantage of the great difference between the solubilities of the oxidized and reduced forms of the cytochrome.

The partial purification of *P*-cytochrome$_{551}$ by the first four steps has been described[1]. Using the resulting sample, zone-electrophoresis was carried out on a vertical column packed with potato starch (3 cm. in diameter, 30 cm. in height) under the following condition: 0·1 *M* sodium phosphate buffer, *p*H 7·0; current, about 20 m.amp. (350–400 V.); temperature, 4–5° C. The sample was placed in the middle of the column in a concentrated solution. Soon after the beginning of electrophoresis, a lot of brown impurities, not removed by treatment with rivanol, migrated downwards (anode) fairly rapidly, while the *P*-cytochrome$_{551}$ remained near the starting line. After 40 hr., the column was fractionated with the same buffer, using the same method as for normal resin columns. The brown impurities were eluted first and so could be removed easily. Nothing was eluted out after the cytochrome-containing fractions. The fractions of cytochrome were collected and their *E*(red.550·5)/*E*(oxid.275) ratios were found to be higher than 0·90 (this is the ratio of extinction at 550·5 mμ in the dithionite-reduced form to that at 275 mμ in the oxidized form).

The cytochrome collected was then oxidized by addition of the minimum amount of potassium ferricyanide, and precipitated with ammonium sulphate. The precipitate was washed with 80 per cent ammonium sulphate and dissolved in a small amount of distilled water (*E*(red.550·5), 40–60). Solid ammonium sulphate was added to the solution until it became slightly turbid (about 30–35 per cent saturation) and then it was immediately centrifuged. By this procedure, a small part of the cytochrome was precipitated, indicating a suitable concentration of ammonium sulphate for the following procedure. The deep red supernatant was reduced by the addition of a small amount of sodium dithionite, this reduction immediately causing a great increase in turbidity. After the yellowish-red solution had been kept overnight in a refrigerator, it was centrifuged. In most cases, the precipitate consisted of small, but fine needle-like crystals of *P*-cytochrome$_{551}$. The crystalline precipitate was dissolved in a small

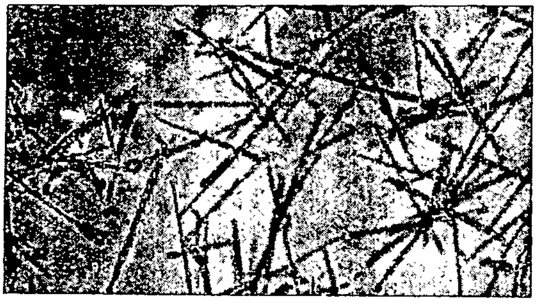

Fig. 1. Crystals of *Pseudomonas* cytochrome$_{551}$. (× 800)

amount of distilled water. After the re-addition of a trace of sodium dithionite, solid ammonium sulphate was added to give slight turbidity, with frequent adjustments of the *p*H to 7–8 with ammonia. The solution gradually increased in turbidity and the needle-like crystals shown in Fig. 1 began to appear after a few hours storage. The addition of the ammonium sulphate and the storage should be carried out at almost the same temperature, since the solubility of *P*-cytochrome$_{551}$ in ammonium sulphate solution increases greatly as the temperature decreases.

Twice recrystallized *P*-cytochrome$_{551}$ had the absorption spectrum shown in Fig. 2, and more than two recrystallizations did not increase its purity.

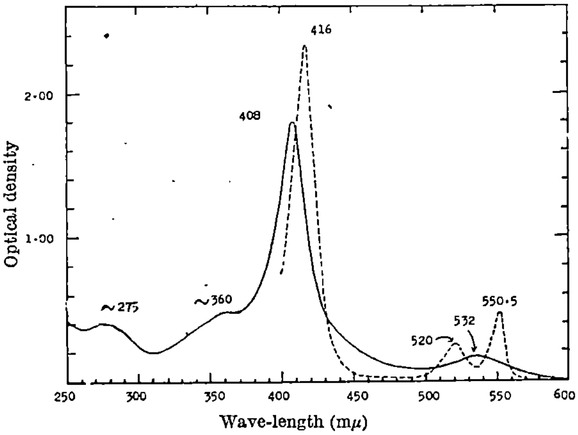

Fig. 2. Absorption spectrum of crystalline *Pseudomonas* cytochrome$_{551}$. ———, Oxidized form; – – – –, dithionite-reduced form. The numerals in the figure are the absorption maxima

Compared with crystalline cytochrome *c* prepared from bovine heart muscle[4,5] the α-absorption peak was at a slightly longer wave-length (about 0·5 mμ). The twice recrystallized sample of *P*-cytochrome$_{551}$ was homogeneous both by electrophoresis and by ultracentrifugal analysis.

Action of Micrococcal Phosphodiesterase on Tobacco Mosaic Virus Nucleic Acid

Cunningham, Catlin and de Garilhe[1] were the first to report the occurrence of a calcium-activated nuclease in the culture medium of *Micrococcus pyogenes* var. *aureus*. These authors partially purified the enzyme and studied its action on deoxyribonucleic acid. In the complete digest they reported the presence of mononucleoside 3′-phosphates and also oligonucleotides. The latter were not identified except for one dinucleotide, deoxyadenylyl-(3′-5′)-deoxycytidine 3′-phosphate[2]. Recently, it was further demonstrated that this enzyme, when activated with calcium, hydrolyses ribonucleic acid[3].

This enzyme has been purified in this laboratory a hundredfold and its action on tobacco mosaic virus nucleic acid was studied. Our enzyme preparations also require calcium ion for activation. Among the reaction products formed after exhaustive digestion of tobacco mosaic virus nucleic acid with this enzyme the following mono- and di-nucleotides have so far been identified: adenosine 3′-phosphate; guanosine 3′-phosphate; cytidine 3′-phosphate; uridine 3′-phosphate; adenylyl-(3′-5′)-cytidine 3′-phosphate; adenylyl-(3′-5′)-guanosine 3′-phosphate; uridylyl-(3′-5′)-guanosine 3′-phosphate; and uridylyl-(3′-5′)-uridine 3′-phosphate; adenylyl-(3′-5′)-uridine 3′-phosphate; and uridylyl-(3′-5′)-cytidine 3′-phosphate. This enzyme has no action on purine or pyrimidine cyclic nucleotides, and hence the possibility of its cleavage of ribonucleic acid via transphosphorylation can be excluded. Full details of this investigation will be published elsewhere.

I wish to thank Dr. W. M. Stanley for his interest and Miss Patrice J. Driskell for supplying me with the organism used in these studies. This investigation was aided by grants from the Rockefeller Foundation and the United States Public Health Service.

Isolation of $\Delta^{5,7,9}$-Œstratrienol-3-one-17 from the Urine of Pregnant Mares

$\Delta^{5,7,9}$-ŒSTRATRIENOL-3-ONE-17 was isolated from pregnant mares' urine in 1940 by Heard and Hoffman[1]. These workers obtained approximately 160 mgm. of pure material per 10,000 gallons of urine, that is, about 3·8 μgm./l., but stated that this did not represent the total quantity excreted. Since no other isolations of $\Delta^{5,7,9}$-œstratrienol-3-one-17 from pregnant mares' urine have been reported in the literature, we believe that it is of interest to record that we have found the material to be present in pregnant mares' urine in relatively large quantities (approximately 430 gm. of $\Delta^{5,7,9}$-œstratrienol-3-one-17 per 10,000 gallons of urine, that is, about 10 mgm./l.) and that we have isolated the material readily in the pure state.

A concentrate, representative of mares' urine collected from approximately the fourth to ninth month of pregnancy, was prepared by methods previously outlined by us[2]. The concentrate was subjected to hydrolysis and a non-phenolic ketonic fraction isolated which yielded, after acetylation, approximately 100 gm. of pure $\Delta^{5,7,9}$-œstratrienol-3-one-17 acetate on repeated crystallizations. This acetate had the following properties: m.p. 167–69° C.; $\lambda_{max.}$ (alc.) 269 mμ, $\varepsilon = 395$; $\bar{\nu}_{max.}$ (CS_2) 1,736 cm.$^{-1}$ and 1,242 cm.$^{-1}$ (acetate), 810 cm.$^{-1}$ (aromatic ring *B*). The infra-red spectrum was identical with that of a sample of $\Delta^{5,7,9}$-œstratrienolone acetate kindly supplied by the late Prof. R. D. H. Heard. On hydrolysis with perchloric acid in methanol at room temperature an 85 per cent yield of the free alcohol was obtained. This had a melting point of 146–49° C., and had bands in the infra-red (CS_2) at 1,741 cm.$^{-1}$ (17-ketone) and 811 cm.$^{-1}$ (aromatic ring *B*).

Vitamin B_{12} Activity in the Serum of the Rat

A STUDY is being made in this Department on the metabolism of vitamin B_{12} in the albino rat, and on the effects of deficiency of this vitamin produced by dietary and other means. As part of this study, the possibility was investigated of using microbiological assays of vitamin B_{12} activity in serum to assess the nutritional state of the animals with regard to vitamin B_{12} in the same way as in human subjects. This communication describes preliminary results obtained on normal and gastrectomized rats and on rats which had been kept on a diet deficient in vitamin B_{12}.

Albino rats of the Wistar strain were used. Blood (1–2 ml.) was obtained by cardiac puncture and was allowed to clot in small test-tubes. The clots were broken up with glass rods, the samples were centrifuged, and the serum was removed and stored frozen until required for assay. The vitamin B_{12} activity in the serum was assayed by a method described by one of us[1], using *Lactobacillus leichmannii* as test organism. Owing to the small amounts of serum obtainable from rats, protein-free extracts were prepared from 0·4 ml. portions of serum, and assays were carried out at one dilution only, corresponding to 1 ml. of a 1 : 20 dilution of serum per 5 ml. of assay medium. Tests using larger amounts of pooled serum from various groups of animals showed that the values obtained using different dilutions of serum were the same within the limits of accuracy expected from microbiological assays. The method gave quantitative recoveries of vitamin B_{12} added to pooled rat serum (Table 2).

The results obtained in various groups of animals are shown in Table 1. It is evident that both gastrectomy and dietary deficiency of vitamin B_{12} can cause reduction in the vitamin B_{12} activity of the serum to subnormal levels, so that the estimation seems to be useful in deciding whether or not an animal is deficient in vitamin B_{12}.

Table 1. VITAMIN B_{12} ACTIVITY IN THE SERUM OF VARIOUS GROUPS OF RATS

Group	No. of animals	μμgm. vitamin B_{12} activity per ml. serum	
		Mean	Range
Normal	36	983	630–1,500
Gastrectomized (1–12 months after operation)	6	402	350–480
Animals fed a diet deficient in vitamin B_{12} for 6 months	4	515	460–560
Normal (assayed with *Euglena gracilis*)	6	150	100–180

Table 2. VITAMIN B_{12} ACTIVITY OF SAMPLES OF POOLED RAT SERUM BEFORE AND AFTER TREATMENT WITH ALKALI

Sample No.	Group of rats	μμgm. vitamin B_{12} activity per ml. serum	
		Before alkali treatment	After alkali treatment
1	Normal	1,400	460
2	Normal	1,200* 1,300*	550* 530*
3	Normal	830* 730*	450* 370*
3 + 1,000 μμgm. vitamin B_{12} per ml. added	Normal	2,000	420
4	Normal	770	460
4 + 1,000 μμgm. vitamin B_{12} per ml. added	Normal	1,900	490
5	Gastrectomized	430	410
6	Fed diet deficient in vitamin B_{12} for 6 months	610	510

* Results of separate assays on the same sample of serum.

The levels in both the normal and the deficient animals, however, are high compared with those found in normal subjects and patients with untreated pernicious anæmia respectively[2]. This appears to be because rat serum contains a substance which has vitamin B_{12} activity for *Lactobacillus leichmannii*, but which is stable to boiling for 30 min. at *p*H 12, a treatment which destroys vitamin B_{12} and almost all the vitamin B_{12} activity in human serum[1]. Table 2 shows the vitamin B_{12} activity of pooled sera from different groups of rats before and after boiling with alkali. While about 50 per cent of the activity in normal rat serum is destroyed, much less is destroyed in serum from gastrectomized rats and rats kept on a diet deficient in vitamin B_{12}. The alkali-stable fraction, however, is roughly the same in all the groups. This suggests that deficiency of vitamin B_{12} causes a gross depletion of true vitamin B_{12}, the alkali-labile fraction, but that the alkali-stable fraction is unaffected. When serum to which vitamin B_{12} has been added is treated with alkali, the activity remaining is virtually the same as that found after treating with alkali the same sample of serum without added vitamin B_{12} (Table 2).

Estimations of vitamin B_{12} activity were kindly carried out for us on the sera of 6 rats by Dr. W. M. Davidson of King's College Hospital Medical School, London, using *Euglena gracilis* as test organism. The results are included in Table 1. Although *Euglena* gives lower results than *Lactobacillus leichmannii* on human serum, the difference would not account for the discrepancy found with the rat sera, so that the alkali-stable fraction in rat serum may be inactive for *Euglena*. Experiments are in progress to determine the nature of the alkali-stable fraction.

We are grateful to Mrs. Beryl Godfrey and to Mrs. Elisabeth Ross for assistance with the microbiological assays, and to Prof. L. J. Witts for his interest in the

work, which was supported in part by a grant from the Medical Research Council to Prof. Witts.

Effect of Hydrogen Peroxide on Transplanted Rat and Mouse Tumours

Recently, Holman[1] has reported that daily continued oral administration of commercial hydrogen peroxide (in drinking water) caused complete regression of Walker carcinoma 256 in rats in 50–60 per cent of the cases. This laboratory finding was applied in humans with advanced inoperable cancers. In two of the four cases there was reported a definite subjective and objective improvement[1]. The obvious importance of these findings in the case of a compound so plentiful made it desirable to attempt to confirm these results in Walker carcinoma 256 and in several of other animal tumours.

The tumours used in the present study were sarcoma 180, adenocarcinoma *E* 0771, Mecca lymphosarcoma, sarcoma ascites tumour and Ehrlich ascites carcinoma in mice, and Walker carcinosarcoma 256 in rats. The history, biological properties and cytological description of these tumours are given elsewhere[2].

Subcutaneous implantations of tumours were carried out by the usual trocar method. The progress of the tumours in the treated and the untreated animals was recorded graphically by measuring the diameters of the tumours with calipers at weekly intervals for four weeks after tumour transplantation. In the case of ascites tumours[3], intraperitoneal injection of 0·1 c.c. of the fluid containing about one million cancer cells was made into each mouse in the inguinal region. The animals were maintained on a standard pellet diet (Purina Laboratory Chow).

Animals implanted with various tumours were treated by simply replacing their drinking water with distilled water containing 0·3, 0·45 and 0·9 per cent by weight of hydrogen peroxide (U.S.P.). The dilute solutions of hydrogen peroxide were prepared daily. During the experiment, the drinking water-bottles were covered with a tinfoil. The hydrogen peroxide content of the diluted solutions remained practically unchanged after standing 24 hr. in an air-conditioned animal room. The control animals were given water *ad lib.*

The treatment with hydrogen peroxide was started in most cases 24 hr. after transplantation of the tumour, and treatment was continued for four weeks.

The degree of inhibition of the growth of the solid tumours was graded according to the following scheme:

–, No effect; tumour growth more than three-quarters the average diameter of the controls.

±, Slight inhibition; tumour growth from a half to three-quarters the average diameter of the controls.

+, Moderate inhibition; tumour growth from a quarter to a half the average diameter of the controls.

++, Marked inhibition; no tumour growth or growth to a quarter the average diameter of the controls.

The degree of ascites tumour growth was graded according to the following scheme:

–, No effect, indicating marked abdominal distention; the fluid volume increases to three-quarters or more of the controls (16–30 c.c.).

± Slight inhibition, indicating moderate abdominal distention; the fluid volume increases to about a half the volume of the controls (6–15 c.c.).

+, Moderate inhibition, indicating slight abdominal distention; the fluid volume increases to about a quarter the volume of the controls (1–5 c.c.).

++, Marked inhibition, indicating no abdominal distention; no gross ascites.

The results obtained with hydrogen peroxide at various dilutions are summarized below and in Tables 1 and 2. In the tables the average changes in weight in grams of treated over control animals after one week of treatment is recorded. Five or ten animals were used in each test group.

The results of the experiments showed that oral administration of 0·3, 0·45 and 0·9 per cent of hydrogen peroxide in drinking water had no inhibitory effect on the growth of sarcoma 180, adenocarcinoma *E* 0771, Mecca lymphosarcoma and Walker carcinosarcoma 256 in animals. Practically all tumours grew rapidly and killed animals in 2–5 weeks after tumour transplantation. In one experiment the effect of hydrogen peroxide on well-established 12-day-old Walker carcinosarcoma 256 was tested. The results of this experiment showed that daily doses of 0·45 per cent by weight of hydrogen peroxide in drinking water had no inhibitory effect on the

Table 1. Effect of Hydrogen Peroxide in Drinking Water on 1-day-old Mouse and Rat Tumours

Tumour	Hydrogen peroxide content (per cent)	Average hydrogen peroxide water consumed by animal/day (c.c.)	No. of deaths		Average weight change (gm.) treated/controls (1st week)	Results of treatment	
			1st week	2nd week		1st week	2nd week

Table 2. Effect of Intraperitoneal Injections of Hydrogen Peroxide on 1-day-old Mouse Ascites Tumours

Tumour	Dose (mgm./kgm./day)	No. of deaths		Average weight change (gm.) treated/controls (1st week)	Results of treatment		
		1st week	2nd week		1 day	10 days	14 days
Ehrlich carcinoma	15	0/5	2/5	+ 6·4/+ 5·7	–	–	–
Ehrlich carcinoma	75	0/5	0/5	+ 3·8/+ 5·7	–	–	–
Ehrlich carcinoma	150	0/5	1/5	+ 3·0/+ 5·7	–	–	–
Sarcoma 180	150	0/5	1/5	+ 2·1/+ 6·8	–	–	–
Sarcoma 180	225	0/5	1/5	– 0·6/+ 6·8	+	+	+

tumour. All treated tumours grew normally. When the rats were given 0·9 per cent hydrogen peroxide in drinking water, they consumed less water, and therefore ingested an amount of hydrogen peroxide equivalent to that which was contained in 0·45 per cent hydrogen peroxide.

During the course of this work, we determined the effect of hydrogen peroxide on the growth of two different types of ascites tumours, namely, sarcoma 180 and Ehrlich carcinoma. Mice with these ascites tumours die in about fourteen days with large amounts of ascitic fluid. The first intraperitoneal injection of hydrogen peroxide solutions was given 24 hr. after intraperitoneal injection of about one million cancer cells, and the treatment was continued for seven days. From the results in Table 2, it is evident that doses less than 150 mgm./kgm./day of hydrogen peroxide had no inhibitory effect on the growth of either sarcoma 180 or Ehrlich ascites tumours. However, a higher dose of 225 mgm./kgm. of hydrogen peroxide had a moderate inhibitory effect on sarcoma 180 ascites tumour. Treatment of the well-established ascites tumours was less effective.

Incorporation of Carbon-14 Dioxide by Duck Erythrocytes and Reticulocytes *in vitro*

PREVIOUS studies *in vivo* on the incorporation of carbon-14 dioxide from carbonate into rat erythrocytes have demonstrated that this is widespread into globin, hæmatin and ghosts[1]. Some fractions of rat blood rich in reticulocytes can also incorporate carbon dioxide *in vitro*[2].

This communication is concerned with the ability of duck blood rich in reticulocytes to incorporate carbon dioxide *in vitro*.

The blood was obtained in the following way: 30 mgm. phenylhydrazine per kgm. body-weight was dissolved in 10 ml. of saline and administered orally. After 48 hr. about 10 ml. of blood per kgm. body-weight was removed and discarded. After 92 hr. blood rich in reticulocytes was removed for incubation. 50 ml. of heparinized blood (10 mgm. per cent of heparin) was added to a saline solution of penicillin and streptomycin (about 3 mgm. per cent). 200 μc. of NaH^{14}CO$_3$ (1 mc./mmole) dissolved in 5 ml. of an isotonic solution containing 0·4107 gm. per cent of sodium carbonate and sodium chloride, and 0·3 per cent glucose was then added to the mixture. 10-ml. aliquots in 30 ml. vessels were incubated, with slow rotation in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide for 20 hr. at 38·5 ± 0·1° C.

Hæmatin, globin stroma, and protoporphyrin were prepared by the method previously described[2], histone and deoxyribonucleic acid according to Allfrey *et al.*[3]. The total carbon content was determined according to Van Slyke *et al.*[4] and its activity was measured by the gas-phase counting method[1,2]. The results are shown in Table 1.

From these results it can be seen that there is considerable fixation of carbon from sodium bicarbonate during incubation of duck blood with sodium bicarbonate.

Table 1

Materials	Stroma	Globin	Hæm	Protoporphyrin	DNA	Histone
Specific activity (disintegrations/mgm. C/min.)	226	154	45·5	1,430	83	130

Error of experimental results less than 10 per cent

The uptake in our experimental conditions is of the order of a few parts per thousand. Because carbon fixation from sodium bicarbonate in biological systems takes place[5] after dehydration of carbonic acid in equilibrium with HCO$_3^-$, carboxylation reactions are obviously possible in the red cells of the duck.

The widespread incorporation into all the components of red cells we have analysed, suggests that the first products of carboxylation belong to a pool of substances from which all the substances we examined can be synthesized. They could be those of the Krebs cycle[5].

These first products will have a greater specific activity, since they are less diluted with similar labelled compounds. To these products we ascribe the large value of carbon-14 specific activity found in non-protein fractions of the plasma (800 disintegrations/mgm. carbon/min.) and in a hæmolysed fraction containing none of the substances in Table 1 (1,700 disintegrations/mgm. carbon/min.).

The fact that the specific activity of the protoporphyrin is greater than that of the hæm indicates that the protoporphyrin is mainly newly formed by young red cells *in vitro*[6].

The activity found in the globin shows that carbon dioxide is fixed in amino-acids; our present knowledge suggests that it is previously fixed in some keto-acids by carboxylation reactions, and that amino-acids are then formed by transamination. If this is also true for duck red cells, they will contain transaminases. The activity found in the hæm and in the protoporphyrin shows that carbon dioxide is previously fixed in succinate and/or glycine[7]. The specific activity in the hæm is approximately 30 times lower than in the protoporphyrin. From this it can be deduced that for a hæmoglobin concentration of 15 gm. per cent (that is, for a hæm concentration of 0·7 gm. per cent), approximately 20 mgm. of hæm was synthesized in 20 hr.

Adding iron as gluconate to the blood increased the relative specific activity of the hæm (Table 2), as though iron gluconate catalysed the formation of some hæm precursor or inhibited the synthesis of some amino-acid of the globin.

Activity found in the histone shows that there is a nucleoprotein turnover: this result does not conflict with that of Allfrey *et al.*[3], who found no detectable turnover in similar experiments with glycine-^{15}N, in view of the small glycine content of the histone[8] and the sensitivity of their apparatus. The activity found in the deoxyribonucleic acid could also be due

Table 2

Experiment	Relative specific activity	
	Globin	Hæmatin
A (no Fe^{++} added)	1	0·29
B (Fe^{++} added)	1	0·46

Table 3

Time (hr.)	Specific activity in disintegrations/min./mgm. carbon in			
	Globin	Hæm	Stroma	Protoporphyrin
1·5	38	14	41	3,700
3·0	40	18	54	
6·0	50	19	85	3,350
18·0	53	27	107	2,400

Error of experimental results less than 10 per cent

to a direct fixation of carbon dioxide in the purine ring[9].

The specific activity of the stroma was found to be greater than that of the hæmoglobin. This proves that the activity of the stroma is not due only to the residual hæmoglobin trapped; in effect both the protein and the lipid fractions can incorporate carbon dioxide.

Rate of uptake. Incubation was carried out at 38·5 ± 0·1° C. for 1·5, 3, 6 and 18 hr. in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide. Samples of 15 ml. of blood from the same duck were mixed with 60 μc. $NaH^{14}CO_3$ (specific activity 1 mc./mole dissolved in 1·5 ml. of an isotonic solution). 0·7 mgm. of iron as gluconate, 50 mgm. of glucose, 1·25 mgm. each of sodium benzyl-penicillin and dihydrostreptomycin sulphate were also added. The preparation of the materials and the method of measuring the specific activity have already been described[1,2].

The results are shown in Table 3; specific activity values are plotted against incubation time in Fig. 1.

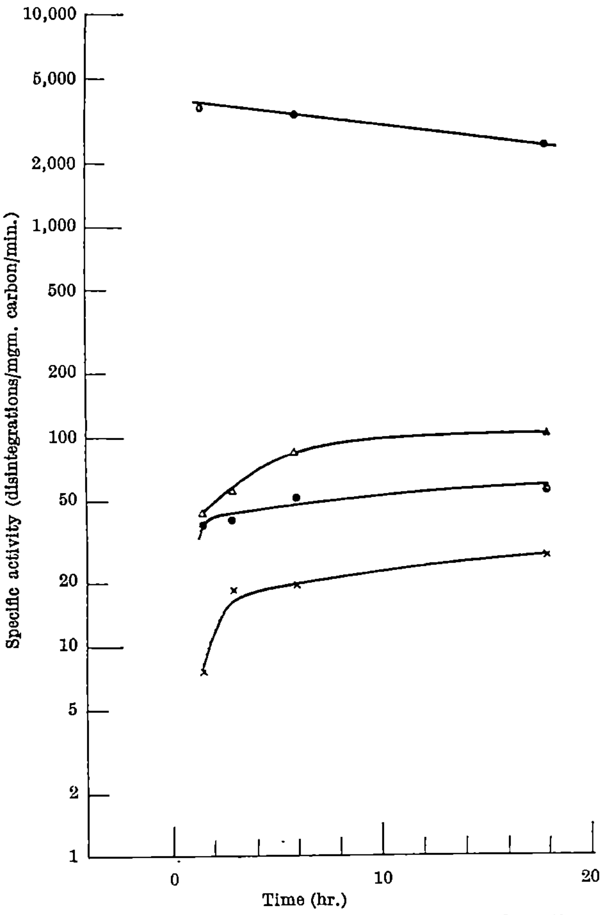

Fig. 1. ○, Protoporphyrin; △, stroma; ●, globin; ×, hæmatin

Carbon incorporation from sodium bicarbonate follows the same pattern, within experimental error, for globin and hæmatin: it can be deduced that the rate of hæmatin and globin synthesis is the same; that is, there is not a different turnover for the two substances. The decreasing rate after the first 4 hr. (in which 70 per cent of newly synthesized hæmoglobin is formed) may be due to a progressive deficiency of amino-acids. Our results on the rate of new synthesis of hæmatin are in good agreement with those reported by Shemin *et al.*[7] on the rate of incorporation of glycine-^{15}N by duck blood in similar experimental conditions.

Carbon uptake from sodium bicarbonate into stroma and into protoporphyrin is different from that seen in hæmoglobin. The specific activity of protoporphyrin decreases slightly with time: this may be due to dilution with less active protoporphyrin arising from the catabolism of the hæmatin.

Further experiments are in progress to extend these results.

Development of Skeletal Muscle Protein

We have reported determinations of the actin and myosin in the skeletal muscle of a chick 72 [1,2] and 96 [3] hr. after incubation respectively. In order to test whether the appearance of actin in the developing skeletal muscle before the formation of myosin is limited to chick embryos or is a general phenomenon in animals I investigated the formation of actin and myosin in the embryonic stages, and in regenerating limbs after amputation at the knee, of *Triturus pyrrhogaster* using the same methods as before.

G-Actin and myosin were isolated from the skeletal muscle tissue of good-sized specimens of *Triturus pyrrhogaster* by the method of Szent-Györgyi[4]. Both proteins, at a concentration of 25 mgm./ml., were injected intravenously into rabbits at three-day intervals, until they reached a total of 100 mgm. The rabbits were bled by heart puncture on the fifth day after the last injection, and the sera obtained were raised to their serological specificity by resorption tests[5] with saline extracts of liver, spleen and skin tissue of *Triturus pyrrhogaster*. Titration with homologous antigen[6] was then carried out before the precipitin reaction with a saline extract of embryo or granulating tissue of amputated limbs. The titre of both sera was 1 : 512. A possible failure due to excess of antigen was prevented by using a constant volume of sera and progressively decreasing the amount of antigen.

It was found that actin and myosin first become detectable in the early embryo at stage 19 (about 132 hr. old at 20 ± 1° C.) and stage 24 (about 176 hr. old at 20 ± 1° C.)[7] respectively (Table 1). They were detected in the granula of regenerating limbs about 20 and 27 days after operation (Table 2) respectively, though DeHaan[8] reported a transient appearance of actomyosin in the regenerating limbs of *Amblystoma mexicanum* about 20 days after operation. His result may be due to a cross-reaction of his antisera with developing actin[9].

Table 1. DETERMINATION OF DEVELOPING SKELETAL MUSCLE PROTEIN IN EARLY EMBRYOS OF *Triturus pyrrhogaster*

Developmental stages	No. of embryos extracted	No. of reactions series	Lowest antigen concentration to give positive results*	
			Actin	Myosin
18	12	2	—	—
19	12	2	1 : 20	—
20	12	2	1 : 40	—
23	12	2	< 1 : 160	—
24	12	2		1 : 160
25	12	2		< 1 : 160
26	10	2		< 1 : 160
Control (non-fertilized)	24	2	—	—

* Antigen concentrations used ranged from 1 : 10 to 1 : 160 in embryos weight.

Table 2. DETERMINATION OF DEVELOPING MUSCLE PROTEIN IN REGENERATING LIMB OF *Triturus pyrrhogaster*

Days after operation	No. of granules extracted	No. of reactions series	Lowest antigen concentration to give positive results*	
			Actin	Myosin
18	10	2	—	—
20	10	2	1 : 20	—
22	10	2	1 : 160	—
25	10	2	< 1 : 160	—
27	10	2		1 : 10
29	6	2		1 : 40
31	6	2		1 : 160

* Antigen concentrations used ranged from 1 : 10 to 1 : 160 in tissue weight.

Therefore, it is probably generally true that in the skeletal muscle actin appears before the formation of myosin, both in the early stages of development and in regenerating tissue. On the other hand, in the heart muscle of early embryos, myosin appears before actin[1,2,10]. In view of this, the morphological and physiological characteristic differences between heart and skeletal muscle should be examined.

Fungitoxic Action of 8-Hydroxyquinoline, Pyridine-N-oxide-2-thiol and Sodium Dialkyldithiocarbamates, and their Copper Complexes

IN a previous communication[1] on the mode of fungitoxic action on *Aspergillus niger*, we found that of the copper complexes of 8-hydroxyquinoline (oxine) and pyridine-N-oxide-2-thiol (PTO), the 1 : 2 complexes are toxic, but of the sodium dimethyldithiocarbamates (NaDDC) the 1 : 1 complex is toxic but 1 : 2 complex is not. We suggested that this discrepancy is not fundamental but can be explained simply by the difference in solubility of the complexes (Table 1). This hypothesis can now be substantiated by observations on the fungitoxic action on *Glomerella cingulata*, a more sensitive mould than *A. niger*. The experiments were carried out as described before[1], in shaken flasks with a basal medium of glass-distilled water and analytical grade reagents, the total copper content not exceeding the equivalent of 0·01 p.p.m. $CuSO_4.5H_2O$. We found that, unlike *A. niger*, *Glomerella cingulata* does not show 'inversion growth' with sodium dimethyldithiocarbamate and copper and, as could be expected on this ground, it is inhibited by copper dimethyldithiocarbamate ($CuDDC_2$) (Table 1). The toxic concentration of copper dimethyldithiocarbamate appeared to be somewhat higher than the concentration of a saturated solution[2], but this can be easily understood since the dissolution is a rather slow process. From Table 1 it follows that for all three 1 : 2 complexes *G. cingulata* is more sensitive than *A. niger*.

The fact that *G. cingulata* is inhibited by copper dimethyldithiocarbamate suggested that for this mould the inhibition pattern for sodium dimethyldithiocarbamate might be the same as for oxine and pyridine-N-oxide-2-thiol. The experimental results summarized in Table 2 lend support to this hypothesis. Moreover, from the known stability constants[3] and the solubility[2] of copper dimethylthiocarbamate, it is easy to calculate, the amounts of the 1 : 1 and 1 : 2 complexes present in each instance. The results were the same as those obtained earlier[1] with *A. niger* for 8-hydroxyquinoline and pyridine-N-

oxide-2-thiol, namely, the toxicity is determined by the concentration of dissolved 1 : 2 complex, provided that an excess of copper is present in the medium in order that the 1 : 1 complex can be formed as well.

When no copper is added, toxicity is still rather high. This may be due to traces still present in the medium. When, however, all copper is bound by addition of 0·3–1 p.p.m. of sodium dibutyldithiocarbamate—a non-toxic agent with stronger chelating properties than the dimethyl compound, 8-hydroxyquinoline or pyridine-N-oxide-2-thiol—the minimal toxic concentrations of these compounds are 20, 5 and 5 p.p.m. respectively. These figures were not lowered by the addition of even fairly large amounts of ferrous sulphate (10–100 p.p.m.). Thus we must conclude that in contrast to the work of Albert and co-workers[4] with bacteria, the iron complexes are not toxic for moulds, as has also been found for 8-hydroxyquinoline by Anderson and Swaby[5].

We have also found that the fungitoxic action of homologues of sodium dimethyldithiocarbamate is determined in a similar way by the solubility of their 1 : 2 complexes with copper and the sensitivity of the test mould. For *G. cingulata* the inhibition pattern of sodium diethyldithiocarbamate (Table 3) is different from that of the dimethyl compound, but equals it for *A. niger*. This is easily understood from the finding that the solubility of the 1 : 2 complex of copper and diethyldithiocarbamate is far less than that of copper dimethyldithiocarbamate, namely, about 0·002 p.p.m. [2]. While the latter is still sufficiently soluble to inhibit *G. cingulata*, the former is not. Consequently, if sufficient copper is added to the medium, we find a zone of inversion growth (1 : 2 complex) and, at lower sodium diethyldithiocarbamate concentrations, a first zone of inhibition (1 : 1 complex). A second zone of inhibition is caused by the free dithiocarbamate (50 p.p.m.), as is the case with dimethyldithiocarbamate.

Thus a difference in toxicity of the 1 : 2 complexes of the methyl and ethyl compounds is found with *G. cingulata*. A difference in the toxic effect of the 1 : 1 complexes can be clearly seen from experiments with *A. niger*. Whereas sodium dimethyldithiocarbamate always shows a distinct first zone of inhibition in the presence of 10 p.p.m. copper sulphate due to formation of the 1 : 1 complex, no inhibition is seen when the diethyl compound is used instead.

This difference does not necessarily point to the diethyl 1 : 1 complex being less active as compared with the dimethyl 1 : 1 complex, for it is clear that a decrease in solubility of the 1 : 2 complex will cause a lower concentration of 1 : 1 complex in solutions of comparable composition.

When the dipropyl derivative is used, the amount of 1 : 1 complex present is much less again than with the diethyl compound. With *G. cingu*
complex causes only some incomplete
0·5–10 p.p.m. of sodium dimethyldit
when 10 p.p.m. of copper sulphate is
medium. The free dithiocarbamate its
be harmless, even at 200 p.p.m. Wit
derivative there is no inhibition up to

In conclusion, we may say that in the
range below 50 p.p.m. the inhibition p
dithiocarbamates is determined by the
the 1 : 2 complex with copper, and t
of the mould.

We thank Prof. G. J. M. van der
interest in this work and for his permiss
these results.

into the compound made the detection
relatively easy, since the organo-mercu
reacted with alkaline dithizone (diph
azone).

Between 2 and 3 gm. of plant materi
in a mortar at room temperature w
of the mercuric chloride reagent (0·1 per
chloride in 40 per cent ethanol and buff
with *M*/5 acetate buffer). Buffering o
was necessary to obtain consistent res
subsequent chromatography. The inso
centrifuged away, the clear filtrate was
dryness *in vacuo*, and the residue was d
minimum quantity of 40 per cent ethan

tography. Excess mercuric chloride in the extracting solvent was essential to ensure complete protection of the thiol group from oxidation. After applying the solution to the Whatman No. 4 chromatography paper, the papers were developed in the descending direction using *tert*-butanol/acetic acid/water (4:1:1 v/v) solvent. Alkaline solvents were found to be completely unsatisfactory. Developing the papers in the butanol solvent for 18 hr. at 25° C. resulted in an identifiable separation of cysteine and glutathione, the cysteine having the greater R_F value.

Detection of the organo-mercuric compounds was achieved by spraying the paper with a solution of dithizone (0·03 per cent) in 0·1 *N* ammonium hydroxide followed by gentle warming. The compounds appeared as discrete salmon-pink spots after drying. This colour was stable only for a day or two in the light but for up to three months in the dark. 10 μgm. glutathione was detectable by this procedure.

The reaction between the thiol group and mercuric chloride appears to be partially dependent on the overall structure of the molecule. Neither *o*-thiobenzoic acid nor 2-thio-ethanol react under the conditions specified, but 2-thio-succinic acid, cysteine, cysteic acid and glutathione react readily. This suggests that the position in the carboxyl group in the molecule is also important in the formation of the complex.

Using this technique the presence of mercaptans other than glutathione and cysteine has been detected in dormant plant seeds. Further details of these results will be published later.

Micro-electrophoresis

I should like to correct the reference to a publication from our laboratory[1] which appears in a recent article[2] entitled "An Apparatus for Micro-electrophoresis of Small Particles". In Table 1 of that article, a value of 1·31 ± 0·02 μ/sec./V./cm. is quoted as the electrophoretic mobility of human erythrocytes obtained with our apparatus. In our paper we stated: "The cell was calibrated using a suspension of human red blood cells, the mobility of which in *M*/15 phosphate buffer solution at *p*H 7·35 is 1·31 ± 0·02 microns/sec./V./cm.". This is the value obtained by Abramson[3] in an extensive study of the mobilities of mammalian blood cells.

Using the rectangular cells, constructed by fusing two optical flats a distance 0·5 mm. apart, it has so far been impossible to measure accurately the cross-sectional area (A) of the cell[4,5]. This is necessary for any absolute determination of mobility values, since the field strength (X) is determined from the equation $X = I/kA$, where I is the current in amperes and k the specific conductance of the dispersion. The cross-sectional area of rectangular cells constructed by cementing glass slides[6] can be measured directly, since the sides are square. The use of such cells has, however, been criticized on the grounds that the use of cement makes cleaning difficult and the unevenness of the surface interferes with the hydrodynamic behaviour of the liquid.

Effect of Hydrocortisone on Mitochondrial Membrane Permeability

Hydrocortisone has been found to inhibit severely oxidative metabolism *in vitro* by normal rat liver mitochondria. Concentrations of 5×10^{-4} *M* and greater inhibit the oxidation of octanoate, L-glutamate and all tricarboxylic acid cycle intermediates except succinate. Similar patterns of inhibition have been reported for other steroids[1-6].

The hydrocortisone used in this study was a purified sample free from metallic contamination. The steroid was dissolved in a minimal volume of re-distilled ethanol and diluted with water to the required concentration. Ethanol controls were included in each experiment.

Failure to inhibit succinate alone of the tricarboxylic acid substrate oxidations indicated that the mechanism of inhibition might involve pyridine nucleotides which are not present in the succinoxidase system. Reversal of the inhibitions could be achieved by addition of the appropriate coenzyme, nicotinamide and reduced glutathione, to the oxidizing system. This suggested either that hydrocortisone interfered with the function of the respiratory co-factors by competition, inactivation or complex formation or that the steroid acted directly on the mitochondrial membrane. Increased permeability of the mitochondrial membranes could lead to the inactivation of pyridine nucleotide-dependent dehydrogenases by loss of the soluble co-factors. 'Ageing' of enzyme preparations has this effect, as has the hepato-toxin carbon tetrachloride[7,8].

Evidence has been presented that steroids can in fact complex with nucleotides[9,10]. However, the present study shows that complex formation is not the inhibitory mechanism.

The activity of pyridine nucleotide-dependent enzymes may be followed spectrophotometrically by measuring the rate of reduction of the nucleotide, which in the reduced state absorbs light strongly at 340 mμ. The rate of substrate oxidation and linked nucleotide reduction by intact mitochondria is proportional to the permeability of the mitochondrial membrane to the passage of nucleotide and substrate which are added externally. Permeability of the membrane may thus be measured by the rate of reduction of nucleotide.

Fig. 1 shows clearly that hydrocortisone greatly increases the rate of reduction of diphosphopyridine nucleotide by intact mitochondria oxidizing L-malate. The increased optical density is neither due to absorption by the steroid nor to reduction of diphosphopyridine nucleotide in a reaction involving hydrocortisone.

Elimination of the semipermeable membrane barriers by suspension of the mitochondria in water instead of 0·25 *M* sucrose abolishes the effect of hydrocortisone (Fig. 2). The steroid neither accelerates nor inhibits the reduction of diphosphopyridine nucleotide under these conditions.

Comparison of the rates of reduction of diphosphopyridine nucleotide in Figs. 1 and 2, with allowance for the addition of twice as much enzyme in Fig. 1, shows that hydrocortisone increases the permeability of mitochondrial membranes to the same extent as suspension of the particles in water. Semipermeability is abolished.

It is thus clearly established that inhibition of oxidative metabolism *in vitro* by hydrocortisone is secondary to the action of the steroid in increasing the permeability of mitochondrial membranes. Loss of selective permeability allows the soluble co-factors of respiration to be leached from the mitochondria, inactivating pyridine nucleotide-linked dehydrogenases unless the lost co-factors are added in excess to the oxidizing system.

Effect of Ethylenediamine Tetraacetic Acid on the Enzyme System of Yeast Cells

THE peculiar property of amino-carboxylic acids like ethylenediamine tetraacetic acid of combining with metallic ions forming stable chelate complexes is now established, and has led to the varied uses of this acid in different industries, such as textiles, paper, leather, etc.[1,2]. Under a programme of investigation of the possible use of ethylenediamine tetraacetic acid in the sugar industry, it has been found that the sugar salt complexes responsible for the formation of molasses, and for the loss of appreciable amounts of sucrose in the sugar manufacturing process, could be broken by this acid, releasing the sugar molecules into the free condition; this led to a higher recovery of sugar[3]. During a series of experiments to investigate the possible use of ethylenediamine tetraacetic

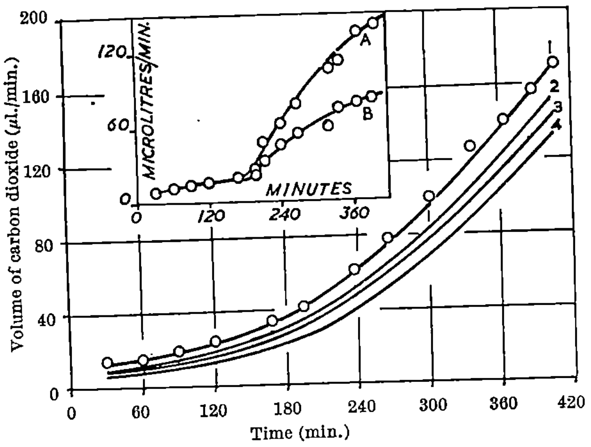

Fig. 1. Time-variation of the rate of evolution of carbon dioxide in the synthetic medium inoculated with yeast cells treated and untreated with ethylenediamine tetraacetic acid. Curves: (1) Yeast cells untreated; (2) treated with 1 per cent ethylenediamine tetraacetic acid for 4 hr.; (3) for 10 hr.; and (4) for 14 hr.

Inset: Curves refer to yeast cells treated with (*A*) 2·5 per cent and (*B*) 5 per cent ethylenediamine tetraacetic acid for 10 hr.

acid for enhancing the yield in the alcohol industry, a few interesting results have been obtained on the effect of the acid on the enzyme system of yeast cells (*Saccharomyces cerevisiae*).

Different samples of molasses obtained from the factories were diluted to 20° Brix; a portion (*A*) of the solution was mixed with the desired quantity (usually 0·25 per cent) of ethylenediamine tetraacetic acid; and the other (*B*) was treated as blank. *A* and *B* were inoculated with yeast and fermented at 30·0 ± 0·1° C. for 72 hr. The amount of alcohol produced, carbon dioxide evolved and yeast formed were estimated by the usual methods. The reducing matter and sucrose content before and after inversion were determined by Somogyi's method[4] which was found by initial experimentation not to be affected by the presence of ethylenediamine tetraacetic acid[5]. Similar experiments were carried out with synthetic media prepared according to White and Munns[6]. In accord with earlier observations[3,5], increased reducing matter and sucrose content were detected in *A*, that is, in the molasses samples and the synthetic media treated with the acid. It is interesting to note that the alcohol formed, carbon dioxide evolved and the yeast produced are markedly less in *A* than in *B*. Thus in one series of experiments, these were respectively 2·23, 6·02, 1·29 gm. in *B* and 2·16, 5·6 and 1·27 in *A*. This difference noted in *A* and *B* is much beyond the experimental accuracy of the methods of analysis. Remarkably enough the amount of sugar consumed during fermentation by yeast in *A* was 7·56 gm. while in *B* it was 6·5 gm. These results indicate that in samples treated with ethylenediamine tetraacetic acid the yeast, while consuming more sugar, gives less ethyl alcohol and carbon dioxide, and suggest that the yeast cells are apparently affected by the acid. This was substantiated by the experiments in which the blank samples of synthetic media *B* were inoculated by yeast which was pretreated with ethylenediamine tetraacetic acid as follows. Well washed yeast cells were suspended in solutions of different concentrations of the acid (in acetate buffer) for varied time-intervals at 5·0° C. and then centrifuged and washed thoroughly. The fermentation was followed up by using Warburg's respirometer. Fig. 1 gives a typical set of results obtained with synthetic media. It may be noted that the amount of carbon dioxide produced decreased markedly with the samples of yeast which were immersed in ethylenediamine tetraacetic acid solution for some time (inset Fig. 1). This is contrary to the favourable effect of the acid noted in the succinic dehydrogenase cytochrome system[7], adenosine triphosphatase[7], papain[8], etc.

Our thanks are due to Prof. S. N. Gundu Rao, director, for his interest and to Dr. N. A. Ramaiah, physical chemist, National Sugar Institute, for helpful discussions.

A Plate Method for estimating the Numbers of Phosphate-dissolving and Acid-producing Bacteria in Soil

In the past, the preparation of plates for detecting phosphate-dissolving bacteria in soil has involved precipitation of the insoluble phosphate in the medium[1-3]. This method is not very suitable for use with the dilution-plate counting technique. For this purpose we have adapted and extended the suggestion of Johnson[4] in which finely divided dicalcium phosphate is incorporated in agar medium. Other forms of insoluble phosphates can also be used as well as insoluble carbonates. We have used calcium carbonate in this connexion for detecting and estimating acid-producing organisms in soil. Stock suspensions of the insoluble substances are prepared by grinding them in a ball-mill in the presence of gum arabic. The latter is necessary to prevent clumping of the finely divided substances during autoclaving.

Stock suspensions of dicalcium phosphate and calcium carbonate are made up at 2·5 per cent (w/v) and 1·5 per cent (w/v) respectively in 0·5 per cent (w/v) gum arabic. After grinding, they are adjusted to *p*H 8·4 before autoclaving and when afterwards added to molten agar medium the suspensions give uniform plates of a satisfactory and similar opacity. For preparation of the plates 1 ml. of the required suspension is added aseptically to 9 ml. of medium held at 45°. For soil counts we have used a modification of Bunt and Rovira's medium[5], containing 0·5 per cent glucose, in which the diammonium hydrogen phosphate is replaced by 0·05 per cent ammonium sulphate and the *p*H adjusted to 6·8. After thoroughly mixing, by hand rolling, the medium containing the dispersed insoluble compound is poured into Petri dishes already containing the 1-ml. aliquot from the appropriate soil dilution flasks. The insoluble compounds in the final plates when examined by X-ray analysis are found to be chemically unchanged. The plates are incubated at 25° C. for 14 days and the total number of colonies

Table 1

Soil	Dicalcium phosphate dissolving organisms (per cent)	Calcium carbonate dissolving organisms (per cent)
Garden	17·9	48·2
Field	16·2	44·7

and those showing halo production counted. Table 1 gives the results obtained from a field and garden soil.

It can be seen that there is a much higher percentage of acid-producing than phosphate-dissolving organisms, showing that not all acid producers can dissolve insoluble phosphates in soil. Increasing the calcium carbonate to the same concentration as the dicalcium phosphate in the plates (0·25 per cent) did not affect this result. Other forms of insoluble inorganic phosphates tried included freshly precipitated hydroxy-apatite as prepared by Sperber[3]. This did not give as high counts as were obtained with dicalcium phosphate.

It should be mentioned that the technique probably gives an under-estimate of the total numbers of phosphate-dissolving organisms in soil as it is too insensitive to detect those dissolving very small amounts. However, when a comparative study of a large number of soils is required the method has been found to be very convenient. Full details of the results obtained with it and other work on bacteria dissolving phosphate will be published elsewhere.

We are grateful to Mr. W. A. Mitchell of this Institute for carrying out the X-ray analyses.

Aerobic Transformation of Cysteine to Sulphate in Soil

MUCH of the sulphur in soils under pasture in humid and semi-arid regions is in the organic form[1,2], and plants are largely dependent on the conversion of this sulphur to sulphate for their nutrition. At the present time little information is available regarding this transformation in soil. Studies conducted with pure cultures of various soil micro-organisms suggest that, under aerobic conditions, sulphate, sulphur, or hydrogen sulphide may be end-products in the decomposition of organic sulphur compounds. Excellent reviews of this work have been published[3,4].

In order to gain information of the reaction sequence carried out by the mixed flora of a typical 'humid' soil, the oxidation of cysteine was observed using a perfusion unit of the type described by Lees and Quastel[5].

A 0·01 *M* solution of cysteine was perfused through 30 gm. of soil held in the perfusion unit, and samples were removed for qualitative paper chromatographic analysis at two-hourly intervals over a period of three days. Oxidation of the cysteine during chr
was prevented by the use of N-ethyl-ma
amount of cysteine and cystine in the p
determined quantitatively by the meth
by Snell and Snell[6].

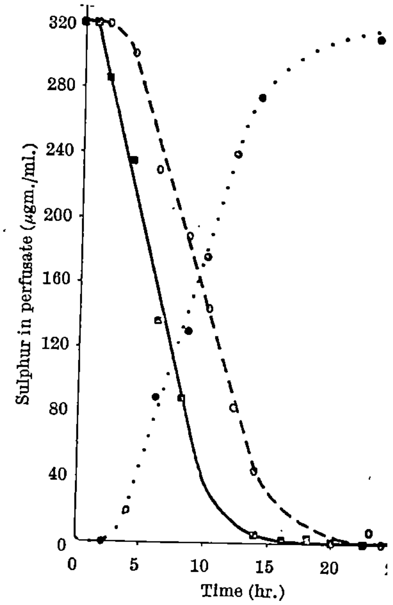

Fig. 1. Conversion of cysteine to cystine in
– – –, Disappearance of cysteine sulphur; . . . .,
production; ——, disappearance of cysteine
solution 0·01 *M* with respect to azid

Cystine and cystine disulphoxide we
identified on the chromatograms. Tau
detected. The identity of cystine
was established by co-chromatography c
the perfusate with the authentic chemical
of solvent systems.

The conversion of cysteine to cystin
rapidly (Fig. 1). In the presence of az
version was somewhat more rapid than
was not added. The acceleration of this re
presence of azide is not explained, but t
it proceeds under these conditions sugge
non-biological. Cysteine did not appea
formed from cystine, as it could not be
the perfusate by paper chromatograph
first twenty-four hours.

30 gm. of soil were enriched with mic
carrying out the oxidation of cysteine
by perfusion with 200 ml. of 0·01 *M* cyst
sulphate production was plotted agai
curve with the typical lag phase of
organisms was obtained (Fig. 2*A*). The

water, and solutions of possible intermedi
fused through the enriched soil, and su
duction again measured.

When cystine and cystine disulphoxid
fused through an enriched soil, their su
duction rate curves did not show the
exhibited by cysteine when it was perfus
fresh soil (Fig. 2). Again, when solutio
compounds were perfused through fres
sulphate production rate curves were sim
obtained for cysteine (Fig. 2*A*). It appea
population present in the enriched soil v
of oxidizing cystine and cystine disul
sulphate, and that these two compounds

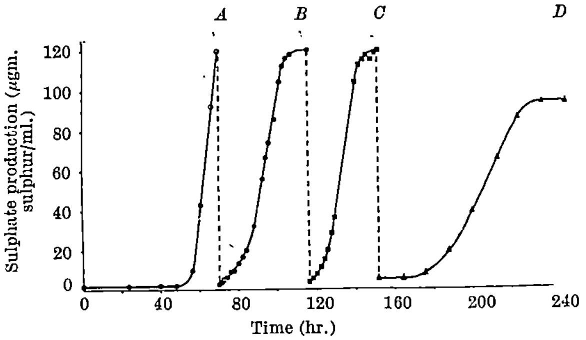

Fig. 2. *A*, 0·01 *M* cysteine solution perfused through 30 gm. fresh soil; *B*, soil from *A* washed free from sulphate then re-perfused with 0·002 *M* cystine hydrochloride solution; *C*, soil from *B* freed from sulphate then perfused with 0·002 *M* cystine disulphoxide hydrochloride solution; *D*, soil from *C* freed from sulphate then perfused with 0·004 *M* taurine solution

intermediates in the transformation of cysteine to sulphate.

Taurine, however, which could not be detected in the perfusate by paper chromatography, was not immediately oxidized to sulphate when perfused through an enriched soil (Fig. 2*D*).

The results obtained here indicate that the transformation of cysteine to sulphate in soil follows the sequence: cysteine→cystine→cystine disulphoxide→ cysteine sulphinic acid→sulphate. Although cysteine sulphenic acid has been suggested as an intermediate in the production of sulphate in animal metabolism[7-9], in our system, if it is formed, it would be derived from cystine disulphoxide and not directly from cysteine.

Part of the work reported here was carried out at the Kearney Foundation of Soil Science, University of California, Berkeley, during the tenure of a Commonwealth Scientific and Industrial Research Organization (Australia) Studentship.

Effect of Gibberellic Acid on the Nodulation of White Clover (*Trifolium repens* L.)

In a recent communication, Thurber, Douglas and Galston[1] reported that spraying of dwarf beans (*Phaseolus vulgaris*) with potassium gibberellate greatly decreased nodulation and they indicated the need for caution in the application of gibberellins to leguminous plants. Probably the most widely used legume in Britain is white clover (*Trifolium repens*), and it is therefore of interest to note the effect of gibberellic acid on the nodulation of this plant.

Table 1

	No. of nodules per plant
Control	11
Gibberellic acid incorporated in agar and added gibberellic acid	11
Added gibberellic acid only	10

Experiments were carried out in both agar and in soil culture. The nitrogen-free agar culture technique was that previously described[2], there being one plant per tube. Ten tubes were set up with 20 p.p.m. gibberellic acid incorporated in the agar-rooting medium and a further 1 ml. of 20 p.p.m. solution added when the seedlings were transplanted; ten more tubes containing the ordinary agar-rooting medium had 1 ml. of 20 p.p.m. gibberellic acid solution added at transplanting; and there were ten control tubes with no gibberellic acid. The plants were allowed to grow for ten weeks in a cool greenhouse and then harvested. That the gibberellic acid was active was shown by the typical effects on the plant, namely, marked elongation of the hypocotyl and leaf petiole.

In the soil experiment, the clover plants were grown from seed in 3½-in. pots, each pot containing 230 gm. of John Innes compost. Each pot of soil was inoculated with 1·25 ml. of a suspension of *Rhizobium trifolii* (strain 157) containing approximately 260 million bacteria per ml. When the plants had reached the two-leaf stage they were thinned to eight plants per pot. At the three-leaf stage 15 pots of plants were sprayed to dripping point with a solution of 50 p.p.m. gibberellic acid containing 0·1 per cent 'Tween 80' as a spreader. A further 15 pots of plants were sprayed with water containing 0·1 per cent 'Tween 80' as controls. The treatments were repeated ten days later. The plants were harvested sixteen days after the last treatment, by which time the control plants had reached the 10–12 leaf stage. The treated plants were showing a marked increase in petiole length and in leaf area, but a reduction in leaf number to 5 or 6 leaves per plant. The nodules were counted and their dry weights determined. Each reading is the mean of 120 plants.

All plants were well nodulated and the nodules were large and pink in colour, indicating that they were effective. One point of interest, not related to nodulation, was that of a further 30 pots of treated plants left for observation, 15 were showing inflorescence formation some 50 days after treatment and only 2 out of 30 untreated were at a similar stage of development.

The effect of gibberellic acid on the growth of the nodule-forming organism was also tested using a turbidimetric method and growing the organism in wheat extract[3] and sauerkraut[4] media. The concentrations of gibberellic acid used were 1, 25, 50, 100 and 1,000 p.p.m. and readings were taken daily for 14 days. None of the concentrations used had any adverse effect on the growth of *Rhizobium trifolii* (strain 157).

Table 2

	No. of nodules per plant	Dry weight of nodules per plant (mgm.)
Plants sprayed with gibberellic acid	20	3
Plants sprayed with water	21	3

It would appear, then, that gibberellic acid, when used in the quantities indicated, has no adverse effect on the nodulation of white clover either in aseptic agar or in soil culture or on the growth of the nodule-forming organism.

Thanks are due to J. Anderson and C. McCombie for technical assistance and to Plant Protection, Ltd., which supplied the gibberellic acid for experimental purposes.

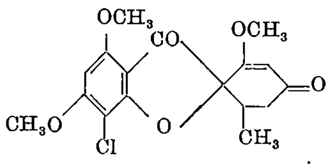
Some Cytological Effects of Griseofulvin

Griseofulvin is a fermentation product of three species of *Penicillium*—*P. patulum*, *P. griseofulvin*, and *P. janczewskii*—which, in very low concentration, suppresses growth and induces striking changes in the hyphæ of a number of fungal species[1].



Griseofulvin

In laboratory mammals the lethal dose is high; Wistar rats of either sex tolerate a daily dose of 2 gm./kgm. given intraperitoneally in aqueous suspension for several days. When the tissues from rats dosed at this level for four days and killed on the fifth were examined histologically, we found the seminal epithelium to be severely damaged and in many places completely necrotic (Fig. 1). The intestinal epithelium also showed abnormalities, but these were less marked. The median lethal dose to rats by intravenous injection is of the order of 400 mgm./kgm. and we have found that some 6 hr. after a single intravenous dose of griseofulvin (100 or 200 mgm./kgm.) a striking arrest of mitosis in metaphase is evident in sites of mitotic activity in the rat. It is very marked in the bone marrow (Fig. 2*a*) and intestine (Fig. 2*b*) and, in rats bearing transplanted tumour (Walker carcinoma 256 or a lymphosarcoma), in the growing tumour tissue. Cells arrested in metaphase show, in varying degree, disorientation and scattering of the chromosomes through the cytoplasm (Fig. 3) such as is seen after colchicine, and in some instances beading or pyknosis of the chromosomes. Interference with mitosis in the bone marrow is reflected in a profound fall in the numbers of circulating red and white blood cells. In rats 24 hr. after this single dose the bone marrow is congested and contains little hæmopoietic tissue; mitotic figures are infrequent but mostly appear normal, while pyknotic and degenerate nuclei are still occasionally seen. In spite of these profound effects the rats appear little affected in general condition and at no stage show very obvious signs of intoxication. Recovery in most of the affected tissues proceeds rapidly after 24 hr., although the effects of interference with spermatogenesis are still discernible in the testes at least 10 days after the single dose.

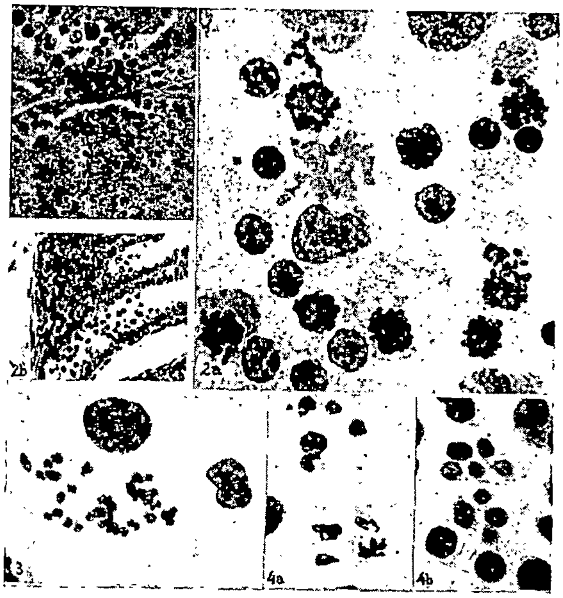


Fig. 1. Section of seminiferous tubules of a rat given griseofulvin intraperitoneally in aqueous suspension, 2 gm./kgm. daily for four consecutive days and killed on the fifth day. Hæmatoxylin and eosin. (×170)

Fig. 2. Tissues of a rat 6 hr. after a single intravenous dose of griseofulvin, 200 mgm./kgm., showing arrest of mitosis in metaphase. *a*, Bone marrow, squash preparation, Feulgen stain (× 600); *b*, intestinal crypts, section, Feulgen. (× 85)

Fig. 3. Bone marrow of a rat after a single intravenous dose of griseofulvin, 200 mgm./kgm., showing at 5 hr. scattering of metaphase chromosomes. Squash preparations, Feulgen stain. (× 600)

Fig. 4. Root-tips of *Vicia faba* after continuous exposure to supersaturated aqueous griseofulvin for *a*, 4 hr., and *b*, 16 hr. Feulgen stain, squash preparations. (× 200)

The true solubility of griseofulvin in water at room temperature is about 10 µgm./ml. Supersaturated solutions containing 20–40 µgm./ml. can be prepared by dissolving in water boiling under reflux (1 hr.), cooling and filtering. Growing roots of *Vicia faba* were immersed in such solutions for varying periods and their tips, fixed either immediately or after varying periods of recovery in tap water, were studied cytologically. Supersaturated solutions of griseofulvin produce some delay in mitosis at metaphase in bean roots within ½–1 hr. of their immersion, but a more striking feature of its action is the induction of multipolar mitosis. In many cells, after separation of the chromatids, the total complement of chromosomes segregates into irregular groups, up to five in number, which are then reconstructed as nuclei of varying size within the original cell (Fig. 4*a*). Cell-cleavage follows in some instances resulting in small mononuclear cells of variable size (Fig. 4*b*). In 'recovery' experiments in which the root-tips were finally exposed to colchicine (0·05 per cent aqueous for 4 hr.) before fixation a small number of tetraploid cells was seen, but under the conditions of our experiments the agent gives rise to fewer polyploid nuclei than would be expected with colchicine itself.

The effects of griseofulvin upon mitosis in some respects resemble those of colchicine; but in rats, at least, it seems much less generally toxic in doses required to produce equivalent metaphase arrest.

the belief that this agent may prove useful to workers in the field of cytology and genetics.

Gibberellic Acid and the Physiological Genetics of Flowering in Peas

IN peas (*Pisum sativum*) Barber[1] has shown that the *Sn* gene which is dominant for a delay in flowering to a higher node has at least four other pleiotropic effects. The gene induces competence to respond to photoperiod and vernalization; it delays the formation of the first leaf with more than two leaflets; and it causes a small reduction in internode length. The reduction in length is only about 10 per cent of that caused by segregation at the *Le* locus. These effects were investigated by appropriate crosses among the four commercial varieties: Telephone (late flowering, tall: *Sn Le*), Greenfeast (late, dwarf: *Sn le*), Alaska (early, tall: *sn Le*) and Massey (early, dwarf: *sn le*). The crosses have also given some evidence that segregation at the *Le* locus may modify the action of *Sn*, *Le Sn* plants flowering about 0·5 node later than *le Sn* plants in appropriate F_2s. The modifying effect of *Le* is 5–10 per cent of the effect of *Sn*. Segregation at the *Le* locus appears to have no effect on an *sn* background.

Brian and Hemming[2] have shown that segregation at the *Le* locus affects some aspect of the metabolism of the gibberellins. In view of the over-lapping pleiotropic effects of segregation at the *Le* and *Sn* loci, we have made an investigation of the effect of gibberellic acid on flowering in the four varieties. The varieties were combined factorially with two photoperiods (18 hr. and 9 hr.), two vernalization treatments (unvernalized and three weeks at 4° C.), and two gibberellic acid treatments (none and 1 μgm. applied to dry seed prior to germination).

The results for node of first initiated flower are given in Fig. 1. The reaction of the varieties to photoperiod and vernalization is as described by Barber[1], late (*Sn*) varieties flowering at a lower node in long days and when vernalized, while early varieties (*sn*) show no response to either environmental variable. The effect of gibberellic acid is to delay initiation of flowering in all varieties. The mean delay varies from about 0·5 node in Alaska to 1·7 node in Massey, giving a delay in time of about one to three days. Gibberellic acid usually causes considerable abortion of flower rudiments so that the delay in production of open flowers is variable and may be considerably longer than three days.

There is a statistically significant interaction between *Le* and gibberellic acid, the effect of the acid on flowering being less in the tall varieties. Brian[3] has shown similarly that the effect of gibberellic acid in controlling growth in length of stem is less in tall than in dwarf varieties. There are no highly significant gibberellic acid × *Sn* interactions. There is an apparently highly significant gibberellic acid × V interaction in long days. However, this interaction seems largely to be due to the behaviour of Massey, which has proved to be anomalous in this experiment. Further experiments to test in detail the behaviour of Massey to gibberellic acid have given no indication of any effect of vernalization and photoperiod on the delay in flowering induced by the gibberellic acid. These latter experiments included both higher total dose and doses applied after germination to plumule and leaves.

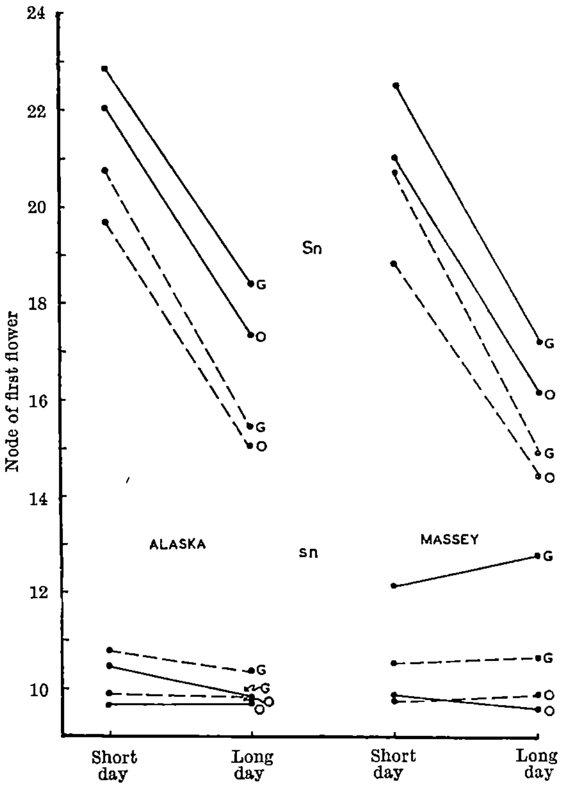

Fig. 1. Effects of gibberellic acid on node of initiation of flowers in four varieties of peas under different photoperiods (short-day, 9 hr.; long-day, 18 hr.) and vernalization treatments (unvernalized; vernalized by 3 weeks at 4° C.). ●– – –●, Vernalized; ●——●, unvernalized; *G*, treated with gibberellic acid; O, untreated

There is some evidence that in *Sn* plants gibberellic acid treatment followed by vernalization may increase the effect of photoperiod. This is in curious contrast to the behaviour of plants not treated with gibberellic acid, where Barber[1] has shown that prior vernalization reduces the photoperiodic response. However, for unknown reasons this competitive effect of vernalization on photoperiod is much weaker in the untreated plants in our experiments. Further experiments are planned to test the significance of these complex interactions.

In addition to the effect on flower-initiation, these experiments have shown that gibberellic acid, like the *Sn* gene, delays the production of leaves with more than two leaflets.

Barber and Paton[4,5] have suggested that the *Sn* gene in peas exerts its effect by producing a hormonal substance which delays the initiation of flowers. Barber[1] concluded that the production of the inhibitor is responsible for the competence of late varieties to respond to photoperiod and vernalization, the inhibitor being selectively destroyed during long days and at low temperatures. The fact that gibberellic acid certainly affects three of those characteristics pleiofirst flower, leaf type, and internode length) and possibly may alter the size of the photoperiodic effect under certain conditions, indicates that the *Sn* gene is probably working, like the *Le* gene, by way of some aspect of the gibberellic metabolism of the plant. It is clear that gibberellic acid is not, itself, the flower-inhibitor produced by the *Sn* gene. However, the production of the flower-inhibitor may be linked to gibberellin metabolism either by way of a common precursor or more indirectly by a reaction involving the production and utilization of the gibberellins.

We wish to thank Dr. P. W. Brian (Imperial Chemical Industries) for the gift of the gibberellic acid used in these experiments. One of us (I. C. M.) wishes to acknowledge the assistance of a research studentship of the C.S.I.R.O. and another (J. I. S.) held the I.C.I.A.N.Z. Research Fellowship of the University of Tasmania. The Rural Credits Division of the Commonwealth Bank of Australia has helped us by providing funds for technical assistance, apparatus and glasshouses.

Effect of Trauma on Wool Growth

A RECENT communication[1] indicated that mechanical trauma such as cutting or scratching the rabbit skin was sufficient to cause a sudden stimulation of hair growth around the site of injury. This effect was observed most dramatically in the quiescent phase of the hair growth-cycle. Because hair replacement in the mouse, rat, and rabbit is discontinuous and occurs in cyclical waves of active growth, Ghadially[1] suggested that the mechanical damage caused quiescent skin to become active and as a result stimulated hair growth. In the case of guinea pigs and man, he reported no gross hair growth-cycle but each hair showed an independent cycle of growth and quiescence. However, he did not indicate whether the hair types from the latter groups would exhibit stimulated growth from trauma.

In our studies on the growth of wool as related to intake of protein, wool samples were collected monthly from tattooed areas on the right shoulder. During the course of sampling we have observed that simple mechanical trauma, as judged by 'bumps' or elevations on the skin, has resulted in a stimulation of growth of wool on the elevated areas. These elevations resulted from the sheep being bumped on the shoulder area as it entered an individual feeding pen. This phenomenon was not noted during subsequent sampling periods and consequently was considered to be of a temporary nature. Wool samples were collected from the elevated area (Sample 1) and from the surrounding area (Sample 2) and 50 fibres were measured for length and thickness. The results are shown in Table 1.

	Sample 1	Sample 2
Crimped length (mm.)	14·0	12·5
Decrimped length (mm.)	18·4 (±1·5)*	17·7 (±1·9)*
Ratio: decrimped length/crimped length	1·3	1·4
Fibre thickness (μ)	20·4 (±3·5)*	17·7 (±2·4)*

* Standard deviation

It is evident from these determinations that there was an increase in the average lengths ($P < 0{\cdot}05$) and thickness ($P < 0{\cdot}01$) of those fibres exposed to trauma when compared with those from the surrounding area. Ghadially[1] has indicated that mechanical damage caused quiescent skin to become active and as a result stimulated hair growth. In the case of sheep it was evident that growth of wool was stimulated although the fibre is a continuously growing filament and not subject to periods of quiescence[2]. Haddow *et al.*[3] and Haddow and Rudall[4] showed that there was a greater density of blood vessels in the skin of rats at the advancing edge of the zone of active hair growth. Durward and Rudall[5] also found that the blood vessel network around the follicle was most dense when the hairs were actively growing, but became reduced during the resting stage of the hair growth-cycle. Ferguson *et al.*[6] deduced that in sheep higher temperatures influenced growth of wool by causing vasodilation and a consequent increased flow of nutrients to the follicle. Ferguson[7] also showed that vasodilation caused by unilateral sympathectomy increased growth of wool on the side of the body in which the nerves had been cut. In view of this it is suggested that trauma, with its concomitant increase in blood supply to the site of injury, stimulated growth of wool.

Isolation and Pure Culture of *Monoblepharis*

ALTHOUGH the genus *Monoblepharis* has been known since 1871 and its species have been collected in many parts of the world[1], there has been no account of its isolation and growth in pure culture, so in 1957 pure culture studies were begun. The investigation is not yet complete, but one of the techniques developed is reported here in view of its possible interest to other mycologists.

The inoculum was derived from natural growths of *Monoblepharis* sp. on twigs of *Quercus robur* L.[1]. Hyphal tufts were teased out under a wide-field binocular microscope, and washed by transference to at least ten successive dishes of sterile distilled water. A small portion of one of these hyphal tufts was then transferred to a cavity slide containing a drop of sterile distilled water and the material observed at a higher magnification (× 500). Tips of hyphæ from a mycelium bearing sexual reproductive organs (by means of which species are identi-

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE, PHILOSOPHY OF SCIENCE GROUP (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. B. Braithwaite: "Identifications as the only Axioms for a Science".

ROYAL INSTITUTION, LIBRARY CIRCLE (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Captain J. L. Pritchard: "The First Centuries of Flight".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the Woolwich Polytechnic Scientific Society, at the Woolwich Polytechnic, London, S.E.18), at 7.30 p.m.—Dr. A. G. Davies: "The Stereochemistry of Some Reaction Mechanisms".

BRITISH PSYCHOLOGICAL SOCIETY (at Birkbeck College, Malet Street, London, W.C.1), at 8 p.m.—Dr. H. Himmelweit: "The Relevance to Social and Child Psychology of a Study of the Effects of Television on Children".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Dr. Paul A. Siple: "South Pole Station".

Tuesday, November 11

UNIVERSITY OF LONDON (at Queen Mary College, Mile End Road, London, E.1), at 1.30 p.m.—Mr. Ritchie Calder: "H. G. Wells".*

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. H. S. W. Massey, F.R.S.: "Exploration of Space".*

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. C. H. Gregory: "Rubber Products for the Motor Industry". 7 p.m.—Mr. S. G. Fogg: "Natural Rubber Compounds for High Temperature Service".

UNIVERSITY OF LONDON (at the Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. S. R. Sparkes: "Engineering Structures—Teaching and Research" (Inaugural Lecture).

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. T. C. F. Stott: "Fatigue Testing of Vehicle Components".

SOCIETY OF CHEMICAL INDUSTRY, CHEMICAL ENGINEERING GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. W. B. Wright and Mr. W. Elland: "The Integrated Iron and Steel Works".

ROYAL AERONAUTICAL SOCIETY (in the Theatre, Park Lane House, 45 Park Lane, London, W.1), at 7 p.m.—Dr. J. Williams: "Boundary Layer Control to Produce High Lift at Low Speeds".

ROYAL AERONAUTICAL SOCIETY, GRADUATES' AND STUDENTS' SECTION (at 4 Hamilton Place, London, W.1), at 7.30 p.m.—Sir Gerard D'Erlanger: "The Air Transport Auxiliary".

Wednesday, November 12

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. W. S. McKerrow and Dr. C. J. Campbell: "The Lower Palæozoic Rocks of North-West Galway"; Dr. J. F. Evernden (University of California): "Potassium/Argon Dating of Tertiary and Pleistocene Rocks".

SOCIETY OF INSTRUMENT TECHNOLOGY, CONTROL SECTION (at Manson House, Portland Place, London, W.1), at 6 p.m.—Dr. P. Fellgett: "Some Applications of Control Technique in Astronomy".

SOCIETY OF CHEMICAL INDUSTRY, CORROSION GROUP (joint meeting with the PLASTICS AND POLYMER GROUP, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. H. G. Cole and Mrs. V. E. Rance: "Plastics and other Polymers as Sources of Corrosive Vapours"; Mr. A. C. Docherty and Mr. H. Hughes: "Plastics for Protection Against Corrosion".

Wednesday, November 12—Thursday, November 13

ROYAL SOCIETY (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 2.30 p.m. on Wednesday and 10 a.m. on Thursday—Discussion on "Space Research" opened by Prof. H. S. W. Massey, F.R.S.

Thursday, November 13

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. A. Maccoll: "Some Impressions of the Colleges in West Africa and the West Indies".*

PHYSICAL SOCIETY, LOW TEMPERATURE GROUP (at the Royal School of Mines, London, S.W.7), at 4 p.m.—Dr. J. M. Lock: "Cryotrons".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Mr. C. B. Winsten: "Geometric Distributions in the Theory of Queues".

INSTITUTION OF MECHANICAL ENGINEERS, HYDRAULICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Flow—the Origin and Nature of Turbulence: Boundary-Layer Occurrences".

CHEMICAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 7.30 p.m.—Prof. Dr. K. Clusius: "Chemical and Technological Aspects of ^{15}N-Chemistry".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at Croydon Technical College, Fairfield, Croydon, Surrey), at 7.30 p.m.—Dr. G. B. Cook: "The Use of Radioisotopes in Industry and Medicine".

Friday, November 14

BIOCHEMICAL SOCIETY (at the National Institute of Medical Research, The Ridgeway, Mill Hill, London, N.W.7), at 2 p.m.—377th Meeting.

INSTITUTION OF MECHANICAL ENGINEERS (in conjunction with the STEAM GROUP, at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Dr. T. Furman and Mr. H. Hampson: "Experimental Investigation into the Effects of Cross Flow with Condensation of Steam and Steam-Gas Mixtures on a Vertical Tube".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. G. G. Gouriet: "Colour Television—Progress During the Last Decade".

Friday, November 14—Saturday, November 15

BRITISH SOCIETY FOR IMMUNOLOGY (joint meeting with the BRITISH ASSOCIATION OF ALLERGISTS, at the Wellcome Building, Euston Road, London, N.W.1), at 2.30 p.m. Friday—Symposium on "Immunological Aspects of Allergic Disorders". Chairman: Dr. D. Blair Macaulay.

Saturday, November 15

BRITISH PSYCHOLOGICAL SOCIETY, EDUCATION SECTION (in conjunction with the ASSOCIATION FOR TEACHERS IN COLLEGES AND DEPARTMENTS OF EDUCATION, in the Assembly Hall, University of London Institute of Education, Malet Street, London, W.C.1), at 10 a.m.—Symposium on "Psychology in the Three-year Teacher-Training Course".

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. R. Bassindale: "The Natural History of Ghana".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

JUNIOR LECTURER or LECTURER, and a LECTURER or SENIOR LECTURER IN THE DEPARTMENT OF BACTERIOLOGY—The Dean, Guy's Hospital Medical School, London, S.E.1 (November 14).

RESEARCH ASSISTANT, for work in the general field of photoconductance, absorption spectra and other electronic properties of ionic solids—Dr. F. C. Tomkins, Chemistry Department, Imperial College of Science and Technology, London, S.W.7 (November 15).

ASSISTANT LECTURER (with special qualifications in stratigraphy and/or palæontology) IN GEOLOGY—The Secretary, The University, Belfast (November 20).

ASSISTANT LECTURER (with special qualifications in applied mathematics) IN MATHEMATICS—The Registrar, The University, Manchester (November 22).

CARTOGRAPHIC DRAUGHTSMAN (able to compile and prepare maps for publication, and preferably geography graduate) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Leeds 2 (November 24).

TEMPORARY LECTURER IN MEDICAL AND VETERINARY ENTOMOLOGY—The Secretary, The University, Edinburgh (November 29).

RESEARCH FELLOW IN PÆDIATRIC PHYSIOLOGY IN THE DEPARTMENT OF PHYSIOLOGY, for the study of problems relating to the physiology of infancy and childhood—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (November 30).

SENIOR LECTURER IN ANATOMY (GROSS ANATOMY) at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 30).

SENIOR LECTURER IN BOTANY, and a LECTURER IN BOTANY—The Registrar, University of New England, Armidale, N.S.W., Australia, or The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (November 30).

LECTURER IN PHILOSOPHY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 8)

LECTURER (competent to lecture in economic geology and structural geology) IN GEOLOGY at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 15).

LECTURER (with an honours degree in mathematics) IN MATHEMATICS WITHIN THE DEPARTMENT OF EXTERNAL STUDIES, University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 15).

RALSTON PROFESSOR OF ZOOLOGY in the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 15).

READER IN AERONAUTICS at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 15).

RESEARCH FELLOW (with a good knowledge of electronics) IN THE DEPARTMENT OF PHYSICS, University of New England, Armidale, N.S.W., Australia, to engage in a research programme on spark discharges in association with Prof. J. M. Somerville—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 18).

Professor of Forestry—The Registrar, University Registry, Oxford (December 24).

Chair of Botany—The Registrar, The University, Hull (December 31).

Chair of Philosophy in the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, December 31).

Reader or Senior Lecturer in Clinical Physiology at Makerere College (University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 1).

Fisheries Officer (with a university degree in marine biology and suitable postgraduate experience) in the Department of Agriculture, Bahamas, to advise on fisheries conservation, introduce new fishing methods, and enforce the fisheries laws—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/27/04.

Plant Pathologist/Virologist (with a good honours degree in a biological science and postgraduate training or experience in plant virus work) at the West African Cocoa Research Institute, Sub-station Ibadan, Nigeria, to carry out research on plant pathological problems relating to cocoa—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD/197/200/017.

Research Assistant (chemistry graduate), to study anionic polymerization with emphasis on reaction mechanisms of stereospecific systems—The Head, National College of Rubber Technology, Northern Polytechnic, Holloway, London, N.7.

Research Assistant (male or female) in Biochemistry—The Medical Superintendent, Western General Hospital, Edinburgh 4.

Research Technician, to work on biochemical problems in a diabetic clinic and laboratory—The Personnel Officer, St. Thomas's Hospital, London, S.E.1.

Senior and Junior Physicist in the Physics Department—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C.1, marking envelope "Physicist".

Senior Lecturer in Electrical Power, a Lecturer in Electrical Circuits and Machines, and an Assistant Lecturer in Electrical Engineering—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

INTERNATIONAL CO-OPERATION IN SCIENCE AND TECHNOLOGY

PERHAPS the most outstanding feature of the first International Conference on the Peaceful Uses of Nuclear Energy held in August 1955 was the way in which it was regarded by scientists as re-establishing the old spirit of scientific co-operation, and promoting in this field both the contact between scientists which had largely been interrupted and the conditions for the free exchange of ideas upon which scientific advance depends. There has since been a notable increase in the release of information in this field which had been classified as secret, and the establishment of the Eurochemie company and the European Nuclear Energy Agency would scarcely have been possible unless scientists and technologists were relatively free to co-operate and discuss common problems. Moreover, it has become even clearer in the past three years that, in nuclear science, equipment is so costly that only by a co-operative effort can we expect to keep the units in economic use or even provide the resources to construct them.

Nevertheless, in his opening address to the second International Conference on the Peaceful Uses of Atomic Energy on September 1, Prof. Francis Perrin, who began with a reference to the value of co-operation and the stimulus to scientific development and to the improvement of education generally and especially to scientific and technical training which was likely to be the first gain to any country from nuclear energy, found it necessary to stress the foolishness of continued secrecy. These international conferences, he said, render great service to the cause of peace by reducing the barriers of secrecy in vast areas of scientific and technological activity. They gave governments a favourable opportunity to declassify areas of knowledge and thus reveal secrets which are found to be largely identical, though the discoveries have been made independently.

This demonstration of the wastefulness of secrecy in itself leads to the removal of restrictions on further areas of knowledge. The wide interest taken generally in this strictly scientific and technical conference, however, offered Prof. Perrin an unrivalled opportunity, which he did well to use, to explain why it is so important to remove so far as possible the secrecy which, since the Second World War, veiled scientific activities in which exchanges of ideas and publications were formerly free. His exposition of the harm done by secrecy, the loss it causes to humanity, and its limited advantages to those who impose it and the serious drawbacks that result even for them, was addressed not primarily to the scientist but to the politician, and to the world generally, which is so profoundly interested in the industrial uses of nuclear energy.

The most obvious disadvantage of secrecy is its adverse effect on the progress of the sciences where it is introduced, by limiting the exchange of ideas and knowledge to more or less restricted groups, and by requiring each group thus isolated to carry out or repeat all the exploratory and methodological work which could have been shared. This is particularly serious for the weakest groups, as they are condemned to an increasing delay which may eventually render their work sterile; but it also adversely affects the strongest groups, since they are deprived of results that could have been obtained by other less well-endowed groups if they had been kept well-informed and so could have worked along neglected directions rich in possibilities. Even in a situation of abundant scientific and technical man-power, there can never be enough available to explore all the attractive and potential avenues. In the situation of scarcity which characterizes the whole Western world at least, progress in nuclear energy and in any other field depends on our ability to make the fullest possible use of all available knowledge and the elimination so far as possible of all overlapping and duplication of effort. The recent conference should have reminded Great Britain in particular of the importance of concentrating her resources on a few carefully chosen projects rather than diffusing them over too wide a field.

No less important, and particularly in reference to the more creative work at the frontiers of an advancing science or technology, is the harm which secrecy does to all groups by excluding the salutary criticism which often comes most effectively from independent groups. Nor is it simply that such criticism can prevent costly mistakes. It is often a stimulus to new ideas, particularly at the meeting place of different disciplines. Finally, as Prof. Perrin notes, the existence of secrecy may deter the most valuable and creative minds from entering such fields of research.

This retarding of scientific progress he regards as only the least of the evils of secrecy in important sectors of research. It also prevents science from acting as the link between men that its universal character enables it to provide: on the contrary, it engenders distrust and poisons human relations in the sphere where they best allow an intermingling of civilizations. Even in the sphere of Anglo-American relations, misunderstanding and friction have been caused by secrecy, and co-operation has been seriously hindered.

Prof. Perrin may tend to over-estimate the contribution which science can make to international co-operation when he characterizes mutual distrust as the most harmful effect of secrecy. Nevertheless, the activities of the international scientific unions and of the special agencies of the League of Nations between the two World Wars showed that it can exert an important influence; and he is undoubtedly right in referring also to the influence in the formation of character of the practice of the disciplines of scientific research and of teaching the sciences, or even of a severe scientific upbringing. Science requires a perfect sincerity with oneself as well as with others, an objective pursuit of truth which goes beyond its own field and penetrates the nexus of relationships between men. It demands a discipline of thought and expression that rejects the empty emotional bombast that is particularly apt to put peoples against each other.

Now, as Prof. Perrin rightly observed, to enclose important fields of research and scientific work, by preventing the men engaged in them from communicating freely with those studying the same problems in other countries, is to lose all the benefit of the mutual understanding and fraternal feeling in the same task that comes with normal relations between scientists. It is a breach, in a limited but important field, of fundamental human freedoms and rights : freedom of expression and information—the right, even the duty, to impart instruction—the right of all to learn and to know all that has been discovered about the mysteries of Nature. We should not exaggerate the importance of this factor—and Prof. Perrin recognizes that we should not expect scientists to differ morally from other men—but when all allowance is made for the effect of that resistance to knowledge which Dr. J. Trenaman stressed in a recent suggestive address to the Library Association, we can ill afford to neglect any means of strengthening co-operation and understanding between the nations. Even from the negative aspect of removing possible causes of friction or distrust, the restoration of normal relations between men working in the various secret fields of research on the use of nuclear energy is a notable contribution to the strengthening of peace.

The importance of this contribution, in Prof. Perrin's view, depends less on the numbers of these men and their part in the development of major national programmes than on their predominant position in the scientists' awareness of their special responsibility to society. Regarding the bringing of men together as the most valuable result of the Conference, he regretted that the Conference is still not fully representative, and that some great peoples are still absent from these exchanges of ideas and this rebuilding of the international scientific community. Until such conferences are fully representative, their contribution to international goodwill and understanding, whatever their intrinsic merits, will be incomplete.

While, therefore, it is appropriate that, on the scientific and technical plane, due thought should be given to the most appropriate and economic intervals at which such conferences should be held, having regard to the considerable interruption of normal scientific and technical effort which they inevitably involve, this other aspect should be kept in mind. No effort should be spared which promises to make such conferences fully representative of the nations. Put at the very lowest level, they help the nations to live peacefully together in this technological age by emphasizing the positive contribution of nuclear energy to human welfare as against the destructive power of nuclear weapons. To the extent that the area of knowledge and understanding of nuclear energy is widened, an inroad is made into the fear and distrust that hinder international co-operation and are a continuing threat to world peace. For its indirect contribution to that end, no less than for its bearing on the advancement of science and technology and on the most effective use of our own limited resources of both equipment or scientific and technical man-power, scientists and technologists in Great Britain should make sure that the points made by Prof. Perrin regarding the foolishness of secrecy are fully apprehended by the Government. Security considerations must not be allowed to hinder the exchange of scientific and technological knowledge beyond the severest limits that independent—and not departmental or subjective—judgment approves ; and this applies not only in Great Britain but also in every other country of the world which is striving for an era of universal peace and prosperity.

SOCIAL CONDITIONS IN ENGLAND AND WALES

A Survey of Social Conditions in England and Wales as Illustrated by Statistics

By A. M. Carr-Saunders, D. Caradog Jones and C. A. Moser. Pp. xxi+302. (Oxford: Clarendon Press ; London: Oxford University Press, 1958.) 25*s*. net.

IN 1927 Sir Alexander Carr-Saunders and Mr. Caradog Jones published the first edition of their "Survey of the Social Structure of England and Wales, as illustrated by Statistics". A second edition, which incorporated figures from the 1931 census appeared ten years later, and the present volume, which has been entirely rewritten, with Mr. C. A. Moser joining the original team of authors, brings the work up to date, using the mass of material that has appeared since the War.

The authors write as social statisticians rather than as sociologists. Their aim is to provide a factual background, to distil the large volume of statistical information that is now available, so that a clear picture emerges for those who are unfamiliar with the pitfalls besetting the interpretation of official data. They aim at avoiding explicit value judgments, so far as possible, and content themselves with description, rather than comment.

The third edition keeps up the high standard set by the two previous ones ; indeed, in arrangement and coverage it has been improved in many ways. Full use is made of the large amount of new information that has been collected as a result of war and post-war policy. The authors' task of selection and summarizing must have been much more difficult than twenty years ago, though the value of their labours is correspondingly increased. For the student of social conditions the book will be an indispensable starting point.

It is interesting to compare the changes that have been introduced in the present edition. There are chapters on nutrition, health, the use of leisure and religion which did not appear in the 1937 edition, though some of these topics will have been treated elsewhere in that volume. The section on personal expenditure has been greatly expanded, using the data collected by the Central Statistical Office, and in the Ministry of Labour's household expenditure inquiry. On the other hand, the chapters on voluntary provision against misfortune, voluntary transfer from rich to poor, poverty, and the inborn qualities of the population have been omitted in the 1958 edition. A comprehensive chapter on social security has been substituted. The sections on education and on crime have been completely recast. The result is a clear picture of social conditions in Britain to-day, in so far as statistics are available to illustrate them. The qualification is important. In spite of the considerable improvement that has taken place in the provision of statistical data, there are still gaps, particularly in social statistics. Thus, the authors comment that national statistics dealing with the distribution of personal property "hardly exist" and figures on personal incomes are "sparse enough". They might have added that income which is liable to and declared for income tax purposes is not always the same as spendable resources. Moreover, most of these data are global in character and it is not possible, as a general rule, to trace the distribution of incomes in particular social or economic groups.

However, the general picture that emerges is that of a society in which inequalities have been reduced, in some cases not inconsiderably, during the past twenty years. There is, however, no ground for complacency on this account. Thus, in the chapter on nutrition it is stated without qualification that the diet of larger households is still inadequate and that some of the deficiencies are not negligible. As regards the ownership of property, the authors quote the Oxford Survey's figure which shows that one-third of all households have no liquid assets at all, a far cry from the picture of a 'property-owning democracy'.

There is one surprising omission: no use is made of the census of distribution to show the structure of wholesale and retail distribution; the auth[illegible]bly regarded this as part of the 'economic' ra[illegible]an the 'social' conditions of England and Wal[illegible]ere is one error which ought to be pointed out [illegible]der to restore peace of mind to happily m[illegible]ried readers of the book. The statement on p. [illegible] that "the longer a marriage has lasted, the greater the chance of divorce" is not correct. The risk of divorce, in fact, decreases after a marriage has lasted for about ten years.

COLORIMETRIC ANALYSIS

Colorimetric Determination of Nonmetals

Edited by David F. Boltz. (Chemical Analysis: a Series of Monographs on Analytical Chemistry and Its Applications, Vol. 8.) Pp. xii+372. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1958.) 8.50 dollars.

This book, Vol. 8, of a series of monographs, may be regarded as supplementary to Prof. Sandell's "Colorimetric Determination of Traces of Metals" (Vol. 3 of the series).

Chapter 1 of the present volume deals quite adequately in twenty-eight pages with principles and practices in colorimetric analysis. Subsequent chapters, written by specialist authors, deal with the individual elements, each chapter being subdivided into sections concerning separations, methods of determination and applications.

The methods described for the determination of phosphorus are those based on the development of molybdenum blue and on the formation of molybdovanadophosphoric acid and molybdophosphoric acid, due attention being paid to possible interferences. Applications dealt with are the determination of phosphate in industrial waters and of phosphorus in steel, serum, and copper base alloys (26 references).

The chapter on silicon deals mainly with applications of the molybdosilicic acid method and the heteropoly blue complex method. Methods for the determination of silicon in various alloys, steel, water, biological materials, foods and agricultural material are described (31 references).

There follows a very comprehensive chapter of 85 pages on nitrogen. A section dealing with Kjeldahl digestion provides a useful summary, including a discussion of the effectiveness of some catalysts, and has applications obviously not limited to colorimetric determinations. The recovery of ammonia by distillation, aeration, and microdiffusion, and all aspects of the Nessler method, are dealt with in considerable detail. Other methods are discussed. Practical details are given for the determination of various forms of nitrogen in water, sewage, biological materials, soil, plants, steel, zirconium and petroleum products, and the sections concerned with nitrite and nitrate include descriptions of methods for the determination of oxides of nitrogen in air (203 references).

The chapter on chlorine is concerned with *o*-tolidine, methyl orange and König reaction methods for free chlorine, nephelometric, silver chromate, silver phosphate and mercuric nitrate methods for chloride, benzidine and nephelometric methods for chlorate, a benzidine method for hypochlorite, and a methylene blue method for perchlorate (37 references).

For the determination of bromine, the colorimetric methods described are preceded by volatilization as free bromine or cyanogen bromide or by oxidation to bromate. The colorimetry is based on König's reaction or on reactions with methyl orange, phenol red, rosaniline, fluorescein or gold chloride. Specific applications described are concerned with the determination of bromine in flour, blood, sea water and brine (34 references).

Preliminary separations dealt with in the chapter on iodine are distillation, extraction by solvents such as toluene, and microdiffusion. Organic matter is destroyed by alkaline ashing or by treatment with acid oxidants, under conditions which are stated to cause no loss of iodine. For the actual determinations, the methods given pride of place and discussed in considerable detail are based on the catalytic effect of iodide on the reduction of cerium-IV by arsenic-III. Probably the average chemist would prefer the more direct colorimetric methods, such as starch–iodine methods (which are also described). Methods based on the extraction of iodide from saturated potassium carbonate solutions and on the oxidation of iodide to iodate by bromine water are not described (127 references).

The chapter on fluorine commences with a discussion of the correct design of apparatus for the Willard and Winter distillation, of the distillation procedure, and of factors that affect quantitative recovery. Other methods of separation receive brief mention. Of all the methods of determination considered, including the zirconium and thorium alizarin methods, a zirconium eriochrome cyanine *R* method is considered most generally suited for photometric analysis. Methods are given for the determination of fluorine in urine, teeth and bones, blood and soft tissues, agricultural samples and water (38 references).

The earlier pages of the chapter on sulphur contain notes on a large number of published methods for the separation and determination of inorganic and organic sulphur. Among methods which receive some detailed consideration are the methylene blue method based on the reaction of sulphide with *p*-aminodimethylaniline in the presence of ferric chloride, and the barium sulphate turbidimetric method. Procedures described in detail include determinations of hydrogen sulphide in gases, of free sulphur in air and in hydrocarbons, of sulphate by benzidine precipitation and diazotization, of sulphur in plants, wool and soils, of sulphides in water and alkalis, and of aliphatic sulphides in hydrocarbons by ultra-violet absorption after reaction with iodine (132 references).

A brief summary of the general chemistry of tellurium and selenium precedes the sections on separations and methods. Following a review, comprising notes on published work, the absorptiometric methods described are based on the formation of iodotellurite, of addition compounds with sulphuric acid, of a compound with diaminobenzidine, and of the tellurium thiourea complex. A colorimetric iodine method for selenium is included. Procedures are given for the determination of selenium in natural waters, copper, steel and arsenic, and of tellurium in lead and copper (46 references).

The chapter on boron commences with notes on precautions, such as avoidance of contamination and loss. Separations are based on distillation as methyl borate, preferably in the cyclic apparatus illustrated. Reactions with quinalizarin, carminic acid, dianthramide or curcumin are used for the actual determinations. Procedures for the determination of boron in steel and alloy steels are given (22 references).

The book contains much very useful information: in general, the treatment is thorough and the choice of methods good.

C. O. HARVEY

THE BILE SOLID

Cholesterol

Chemistry, Biochemistry, and Pathology. Edited by Robert P. Cook. Pp. xii+542. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1958.) 15 dollars.

DR. R. P. COOK must have wondered whether a book of this title could be usefully compiled. He need not have worried: he and his team have done well. The work he has edited is a comprehensive survey of most important work (to the end of 1957) on cholesterol; it includes much material on other sterols and more than a little on steroids in general.

A short historical introduction, appropriately written by Henrik Dam, is followed by a thorough, if condensed, chemical survey by Peter Bladon. This includes sections on nomenclature, on physico-chemical measurements on steroids, on digitonide and other complex formation and on colour reactions. There are tables of natural sterols, and of physical constants (melting points, optical rotations and ultra-violet spectra) of cholesterol derivatives.

R. P. Cook and J. B. M. Rattray then give a chapter on methods of isolation and estimation of sterols; R. P. Cook describes their distribution in organisms and plant and animal tissues. G. S. Boyd and M. F. Oliver discuss the physiology of blood cholesterol and of lipoproteins in man and other species. R. G. Gould thoroughly reviews our knowledge of sterol biosynthesis, and O. Hechter the conversion of cholesterol to steroid hormones. Geoffrey Bourne contributes a thoughtful and provocative essay on the histological demonstration of cholesterol and on its possible functions in cells. Metabolism in the normal animal is dealt with by R. G. Gould and R. P. Cook, and David Adlersberg and Harry Sobotka discuss pathology. The important and highly topical subject of treatment of disorders of cholesterol metabolism is briefly reviewed by I. H. Page. W. Bergmann contributes a chapter on evolution and sterol distribution, Marjorie Horning discusses sterol requirements of insects and protozoa, and Thressa Stadtman writes about microbial metabolism of steroids.

The book ends with R. P. Cook's account of metabolic relationships between cholesterol and other lipids, and there is an appendix on practical methods of extraction, purification and estimation of sterols and lipoproteins.

The book is thoroughly documented throughout, and it has an adequate index. Its format and illustrations are excellent.

More than all this, it is, for the most part, well and clearly written. Dr. Cook has clearly been a tactful and liberal editor; moreover, he and his collaborators have somehow conveyed a sense of history and of the broad sweep of biochemical advance into a work that might easily have been a dry and dull collection of data.

All interested in its subject-matter will want to have an[illegible]ng, will want to read this admirable volume.

G. A. D. HASLEWOOD

STABILITY OF NON-LINEAR SYSTEMS

Differential Equations

Geometric Theory. By Solomon Lefschetz. (Pure and Applied Mathematics: a Series of Texts and Monographs, Vol. 6.) Pp. x+264. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 9.50 dollars.

A STANDARD set of differential equations can be taken in the form:

$$dx/dt = X(x,t)$$

where x,X are n-dimensional vectors, t can be thought of as the time, and a solution $x(t)$ is a curve, or trajectory, in the n-space. This formulation shows the need for some matrix technique and some knowledge of simple topological concepts. The important idea of stability then appears in the statement that a trajectory from a given initial point is stable if, roughly speaking, another trajectory starting from a neighbouring initial point nowhere departs substantially from the former.

After introductory chapters on existence theorems and linear systems, Lefschetz defines various types of stability and examines them in detail for certain important forms of the function $X(x,t)$ such as $Px + q$, where P is a matrix which is either constant or a function of t only, and q is a vector, depending on x and t, which is, in some sense or other, small compared with x. If P is a constant matrix, and q is ignored to get a first approximation, the set of equations is a linear set with constant coefficients, and we may hope that the solution of this simple set will indicate the dominant stability features of the more general set. Much of the content of this section stems from Liapunov's classical monograph on the general problem of stability (1892), but Lefschetz brings the development right up to date by collecting all the salient points from recent research work.

In the latter half of the book, the n-space is specialized to two dimensions. When X is independent of t the equations are said to be autonomous, and in Cartesian form are:

$$dx/dt = f(x,y), \quad dy/dt = g(x,y)$$

The trajectories, which in the autonomous case are called paths by Lefschetz, are studied in considerable detail and much geometrical information about them is obtained, for various special forms of f and g. Then second-order non-linear equations, including the famous van der Pol equation for triode oscillations, are discussed with emphasis on the phase-plane representations: they are reduced to a pair of first-order equations, which may be autonomous, or, as in the case of the Cartwright–Littlewood equation, may contain a function of t on the right-hand side. Finally, there is a chapter on oscillations in a quasi-harmonic system, differing from the simple harmonic equation by a small, variable, perturbation term: Poincaré's perturbation method, and the time-averaging method originated by van der Pol, are described.

Lefschetz's exposition is, as always, vivid and stimulating, and does not demand a great deal of specialized equipment; although some previous acquaintance with matrix notation and the idea of a compact space is desirable, the book itself contains an excellent summary of what is wanted on these topics. In the main sections, the reader will find that he is expected to be quick in grasping new ideas, and should allow himself frequent pauses for assimilation. For the young research student wishing to begin work in this wide and important field, the volume will prove invaluable.

T. A. A. Broadbent

STRUCTURE OF ATOMIC NUCLEI

Handbuch der Physik

Herausgegeben von S. Flügge. Band 39: Bau der Atomkerne. Pp. vi+566. (Berlin: Springer-Verlag, 1957.). 125 D.M.

THIS volume comprises chapters on the two-nucleon problem by Prof. Lamek Hulthén (Stockholm), and Prof. Masao Sugawara (Hokkaido); on the three-body problem in nuclear physics by Prof. Mario Verde (Torino); on the distribution of matter and charge within atomic nuclei by Dr. D. L. Hill (Los Alamos); on the nuclear shell-model by Dr. J. P. Elliott, and Dr. A. M. Lane (Harwell); and on models of nuclear structure by Prof. Steven A. Moszkowski (University of California, Los Angeles).

Profs. Hulthén and Sugawara's contribution, in Chapter 2, gives a complete and compact summary of the experimental data on the two-nucleon problem available up to 1956. The treatment of theoretical questions required for the interpretation of the experimental observations is based on static nuclear potentials as derived from the pseudoscalar field theory. The main merit of this review lies in the careful analysis of the observational data (mostly in the low-energy region) in terms of central forces and the effects achieved when a tensor force is introduced. Sections on high-energy scattering and photo-effect and a mathematical appendix (by Prof. Sugawara) conclude an exemplary piece of scientific reporting. Unfortunately, the recent observations of the polarization of p and n on scattering, of importance in resolving ambiguities in the phase-shift analysis, could not be included. The section on three-body problems and that on matter and charge distribution in nuclei complete what one could call the first part of this volume. Dr. Hill's article illustrates in detail how a single property, such as the finite size of the nucleus and its charge distribution, sometimes has observable effects on a great many atomic and nuclear properties.

The experimental physicist who works in a high-voltage laboratory with a cyclotron and studies the unstable elements will certainly find the second part of the volume dealing with nuclear models particularly welcome. The two articles by Elliott and Lane and by Moszkowski contain everything that the research physicist needs for analysing his data in terms of the mechanism which underlies his observation. It also seems that the review of the shell model is complete in so far as theory is concerned, so that all tools for shell model calculations are at the reader's disposal within its 170 pages; to ease readability, much formal mathematics is placed in eleven appendixes. Dr. Moszkowski's survey of nuclear models offers a lucid and most readable exposé of a mainly non-mathematical character. The general approach is nevertheless that of a theoretician, who ably supports his statements with experimental data. The whole is excellently organized, preventing confusion which could easily arise when one looks at Table 1 with its list of sixteen models. I drew considerable courage from this diversity, since we are not likely to run out of problems during the next five years (though we may do so within ten years), unless Brueckner's theory provides a sudden solution.

Of the total 550 pages in this book, 240 are used for the first three contributions and 310 are devoted to nuclear models. All the contributions are written, in English, by theoretical physicists, 42 per cent of the volume being written by authors working in government laboratories in Britain or the United States, though the topics covered are only remotely connected with the immediate interests of these institutions. They reveal a very high standard of scholarship indeed.

This volume should be within easy reach of all workers engaged on research in the fields covered; it would be so, were it not that the price confines it to libraries, where it will mostly be out on loan. The printing, illustrations and accuracy are of the highest order.

E. Bretscher

RECENT DEVELOPMENTS IN NUCLEAR ENGINEERING*

By SIR JOHN COCKCROFT, O.M., K.C.B., C.B.E., F.R.S.

THE second Geneva Conference on the Peaceful Uses of Atomic Energy revealed the progress in nuclear engineering which has been made during the three years since the first conference.

British experience in operating Calder Hall now extends over two years. The total electrical power generation up to September 1958 has been 938 million kWh., representing a full load power factor of 67 per cent on reactor No. 1 and 81 per cent on reactor No. 2. These high load factors have been achieved in spite of the fact that in this prototype design it is necessary to shut down and release the carbon dioxide pressure before a fuel rod can be changed, this operation taking an appreciable time. During the life-time of the first charge of fuel, only three fuel elements out of the ten thousand developed faults, and so far there has only been one fault in the second charge. In the first charge of reactor No. 2 there have been four positively identified faulty fuel elements, and six channels have been discharged for examination because of rather large signals from the faulty fuel element detector equipment. The fault is usually due to a slight leakage developing in the weld of the magnox alloy can. This allows slow penetration of the carbon dioxide coolant, with resulting oxidization and a slow outleakage of fission products. This usually develops rather slowly, so that fuel elements can be changed when convenient over a period of a week or two. We have had one or two incidences of a more rapid development of a leakage due to a defective weld.

Apart from shutdowns due to the necessity to change faulty fuel elements and to change the whole charge at the end of its life, reactors and power units can go on operating for very long periods; indeed, one reactor operated continuously for six months. Maintenance can be carried out on a single cooling circuit or associated electrical equipment by closing off this circuit and reducing power for an hour or so. There is, in fact, little to go wrong in a graphite-moderated reactor except the fuel elements. No automatic control rod circuits are installed in the Calder Hall reactors, but the circuit has proved to be remarkably stable. The temperature of the fuel element stays constant to ± 1 deg., and there is a similar stability of power-level. In some very large reactors the distribution of power generated in different parts of the reactor can vary slowly over a period of days, due to the accumulation of the fission gas, radioxenon. As a result of this, an increase in power density on one section of the reactor can burn up more xenon and so increase the reactivity, and the opposite effect can occur in another part of the reactor. These very slow spatial oscillations have not so far been observed in Calder Hall.

Initially, with a new charge, the temperature coefficient of reactivity associated with increases of temperature of fuel elements and of moderator is negative and the system is entirely self-stabilizing. As the radiation of the fuel proceeds, the increasing quantity of plutonium fuel modifies the delayed temperature coefficient associated with the moderator temperature, making it increasingly positive; but the prompt coefficient of temperature associated with the fuel-element temperature remains negative. After an irradiation of about 400 MW. days per ton, the moderator temperature coefficient is about $+ 4 \times 10^{-5}$ in K/degree centigrade. It is expected to reach a saturation-level of about 15×10^{-5} with very long irradiation. The overall effect of this limiting value of the temperature coefficient would be that small increases in power-level could be doubled in a time of about two minutes if no movement of control rods were made to correct this. So after a thermal power-level change of 200–201 MW., the level would increase to 202 MW. in two minutes and to 204 MW. in four minutes.

These effects of the positive temperature coefficient occurring over such relatively long periods of time do not require any changes in the normal control of a station, and indeed they are not generally observable to the operator since general small circuit fluctuations require small corrective action to be taken on a similar time-scale. These are examples of the wide range of operational experience we have gained during the past two years. This experience has given us great confidence in this type of power station.

The Shippingport nuclear power station uses a pressurized water reactor to produce 230 MW. of heat, leading to 60 MW. of electricity. This power station went into operation on December 18, 1957, and a brief account of its operational characteristics was given at the recent Geneva Conference on the Peaceful Uses of Atomic Energy. The time taken to get the power station on load from ambient temperature is 8 hr., this being set by thermal stress. The reactor operation has a high negative coefficient of reactivity. On one occasion the condenser vacuum was lost and the turbine shut down automatically. The negative temperature coefficient reduced the reactor output to essentially zero without any movement of control rods, the only effect on the plant being an increase of system pressure from 2,000 to 2,160 lb. sq. in.

The first Russian large-scale nuclear power station came into operation during the period of the Geneva Conference. The power station is to consist of six identical 100-MW. electrical units. The heat source is a graphite-moderated water-cooled reactor, apparently scaled up from the 5-MW. power station reported at the 1955 Geneva Conference. The reactor has pressure tubes of stainless steel to separate the high-pressure coolant from the graphite. The fuel is natural uranium. Steam reaches the turbines at a pressure of 90 lb./sq. in. at 185° C. The power station seems to be a dual-purpose plant. It is the first major contribution to the U.S.S.R. 2,000-MW. programme of nuclear power stations.

None of these three power stations was designed as a commercial nuclear power station. They are either prototypes or dual-purpose reactors, and their capital costs per kW. hr. are high.

---

*Substance of a lecture to the Danish Society of Civil Engineers, delivered on October 6.

The second generation of nuclear power stations are very different. They have usually been designed specifically as power stations for electricity authorities. In Britain they include four graphite-moderated carbon dioxide cooled reactor power stations due for completion at dates ranging from 1960 to 1962 with outputs ranging from 275 to 500 MW. for a two-reactor station. In the United States there are under construction two pressurized-water and one boiling-water reactor power stations having outputs ranging from 134 MW. electrical to 275 MW.(e), the latter being boosted by 110 MW. of oil superheating. In addition, a 100-MW.(e) electrical fast reactor is being constructed. All these are due for completion by the end of 1960. The French are building two graphite-moderated carbon dioxide cooled reactor power stations of 63 MW. and 170 MW., respectively, for completion by about the same period. Italy is to build one British type of power station and one station similar to the U.S. Dresden power station, using a boiling-water reactor as heat source. The Russians are building two 420-MW. stations, each using two pressurized-water reactors. They are also building a 400-MW. power station using four graphite-moderated reactors in which the steam is superheated inside the reactor.

The British stations are typified by the Somerset power station, which is to generate 500 MW.(e). Each reactor contains about three times as much uranium as in the Calder Hall reactors. The pressure of the carbon dioxide coolant is 85 per cent higher than Calder Hall. The fuel element surface temperature is 430° C. compared with 408° C. at Calder Hall. The heat-transfer surfaces of the fuel elements have also been improved over Calder Hall. The effect of this increased pressure, increased temperature and improved surface has been to increase the average rating from the 1·4 MW./ton in Calder Hall, to 2·6 MW./ton at Hinckley Point. This has resulted in reactor capital costs being reduced by about 20 per cent from the first of the four power stations, and is now of the order of £110 per kilowatt exclusive of costs of fuel and site preparation. For the purpose of economic forecast, the fuel elements have been assumed to achieve an average heat output of 3,000 MW. per ton. Reactivity changes due to substitution of plutonium for uranium-235 and accumulation of fission products will not limit the life of fuel elements before appreciably longer burnups. The limit will probably be set at first by metallurgical imperfections. We have so far accumulated experience of burnup of metallic fuel elements to about 1,200 MW. days/ton in Calder Hall. Fuel elements are undamaged at this burnup and we are steadily extending our experience. The Electricity Authority reactors will operate fuel elements at higher temperatures and ratings. The main new phenomenon to be looked for is swelling of the uranium due to collection of fission gases in bubbles. This could lead to appreciable changes of volume, though we do not expect these to exceed about 10 per cent. The magnesium alloy cans have been designed to withstand volume changes of about 25 per cent. Recently we have shown that the observed swelling in small specimens can be much influenced by temperature cycles, and by restraining the amplitude of the cycling the swelling can be substantially reduced.

It has been stated by the Electricity Authority that with a 75 per cent load factor, 5 per cent interest rate and 20-year write off, and a burnup of 3,000 MW. days/ton, the Somerset nuclear power station just about breaks even, since it is situated in an area remote from coal-fields and conventional fuel costs are consequently high.

The American design thought to be most competitive is typified by the Dresden 180-MW. power station. This is served by a dual-cycle boiling-water reactor. The steam – water mixture produced in the reactor core flows from the reactor vessel to a primary steam drum at the reactor pressure of 1,000 lb./sq. in. The steam then flows to the turbine through the primary steam lines, and the water flows to the secondary steam generator where additional energy is removed to produce steam at a low pressure of 500 lb./sq. in. Valuable information on the stability characteristics of boiling-water reactors has been obtained from the experimental boiling-water reactors at the Argonne Laboratory, at Arco and at Vallecitos.

The contract price of the Dresden nuclear reactor was quoted as about £85 per kilowatt exclusive of research and development costs and fuel charges. The actual costs were stated to be higher than the contract price. The Dresden reactor had a fuel charge of 60 tons of uranium containing 1·5 per cent uranium-235 in the form of uranium oxide clad with zirconium. A burnup of 10,000 MW. days/ton is assumed in the economic forecast. Fuel is costed at American prices of the order of £50,000 per ton. and is to be hired at 4 per cent from the U.S. Atomic Energy Commission. The operator has, in addition, to pay for the uranium-235 burnt. On this basis, fuel costs are likely to be at least 3 mils per kWh. and overall costs were stated to be 7·5 mils. Since, however, the actual capital costs were not stated, this does not mean that commercial nuclear power has arrived in the United States. Indeed, it was stated at Geneva that in the United States nuclear power stations could not reach parity with commercial power before the stations which would start to be built in the late 1960's. This reflects the low present cost of power generated from cheap Kentucky coal or natural gas or hydro-power.

In other countries the date for reaching parity will depend on the cost of indigenous or imported fuel, the interest rates and the load factor available. The World Bank reported at Geneva an interesting study in the economics of nuclear power for a 130–150 MW. station to be erected in southern Italy. Bids were obtained from nine industrial organizations in the United States, Great Britain and France. The results were summarized in Geneva. Nuclear power costs for the most favoured bid were expected to be about 10 per cent above the cost of power from oil- (coal-) fired stations using oil (coal) at £9 10s. per long ton. This assumes a return on investment of 14 per cent and a load factor of 80 per cent.

The Geneva Conference also gave a forecast of the developments in progress towards the third generation of nuclear power stations, which may come into operation in the late 1960's. The major United Kingdom objective will be to reduce capital costs 20–30 per cent below those achieved from the improvement in the second-generation power stations. Capital costs can be reduced by increase of rating, so that more output can be obtained for a given volume of reactor. However, the reactor is already contributing less than 40 per cent of the whole cost. Heat exchangers and the conventional power house contribute more than half the cost. So their costs must also be substantially reduced. This can only be done by increasing the temperature of operation and improving steam conditions.

In Britain an advanced gas-cooled reactor nuclear power station is being built as a reactor experiment to produce the advanced techniques which will be necessary to achieve this. The reactor will use uranium oxide fuel canned in beryllium. This should enable surface fuel temperature to be run to 600° C., giving an outlet temperature for bulk gas of between 500° and 570° C. The fuel elements will consist of a bundle of rods of small diameter. The reactor rating will then be increased from the 2·3 MW. per ton at Hinkley Point to about 8 MW. per ton. The reactor experiment will develop 100 MW. thermal and 28 MW. electrical. Since the plant will be purely experimental, a single-pressure steam cycle will be used with the modest steam condition of 600 lb./sq. in. An appreciably higher efficiency should be obtained with the more complex steam cycle which will be possible in the full-scale power station designed to use this advanced technology.

The use of uranium oxide fuel will require a slight degree of enrichment of the uranium—roughly 1·2 per cent of uranium-235 in the reactor experiment and a lower enrichment for full-scale stations. The enrichment could be provided by plutonium oxide from the second generation of nuclear power stations. Uranium oxide fuel is now being intensively studied, and especially valuable reports came from Chalk River. The fuel has great stability to irradiation, though it cracks as a result of thermal shock, so that it relies on the can for restraint. American companies, backed by a guarantee from the U.S. Atomic Energy Commission, are promising a burnup of 10,000 MW. days/ton, and small specimens are reported to have withstood 25,000 MW. days/ton without appreciable damage.

The present Canadian philosophy of power reactor development is to use a heavy-water moderator, allowing natural uranium oxide fuel to be used. It is then hoped to achieve a burnup of the order of 8,000 MW. days/ton and to write off the fuel at the end of the cycle. In this way it is hoped to achieve fuel costs declining from 1·5 mils to 1 mil and so achieve competitive nuclear power in Canada. The heavy-water gas, or water or steam-cooled reactor is undoubtedly one of the serious competitors for a place in the nuclear power station of the future.

We also heard of the progress of three recent experiments employing a different technology. The 10-MW. organic liquid – moderated reactor experiment at Arco uses a diphenyl or terphenyl moderator. This has a comparatively high stability to irradiation, about 100 lb. of polymer being formed per MW. day of heat. Coolant make-up costs 0·75–1·8 mils per electrical kWh., with a present probable value of about 1·2 mils. The use of an organic moderator has the advantage of a low pressure of about 13 atmospheres, with the surface temperature of fuel elements at 420° C. and a temperature of the bulk coolant ranging from 260° to 270° C. Another attractive feature of cooling by organic liquid is the low level of radioactivity of the coolant, which makes possible maintenance of the primary circuit, even during reactor operation. The reactor uses cermet fuel elements consisting of a 20-mil plate of uranium oxide in stainless steel clad in 5 mils of stainless steel. 26 kgm. of uranium-235 are used.

Good operational experience has been reported for this reactor. The system shows considerable promise for ship propulsion and for power stations with output in the 10–30-MW. range. It should have low capital costs, though whether these can be competitive with Diesel propulsion units remains to be seen. Fuel costs at the prices of American enriched fuel and loan charge would be expected to break even with the costs of oil fuel for ship propulsion systems.

The sodium-cooled graphite-moderated reactor experiment at the North American Aviation Company represents another experiment in reactor technology. The use of liquid sodium as a coolant offers the technical advantage of a high operating temperature with moderate pressure. These are offset by the compatibility problems characteristic of liquid sodium and the consequent need to keep the oxygen content at a level of a few parts per million. The graphite moderator has to be separated from the liquid sodium since it is not compatible with it, so that the graphite bricks are canned in zirconium, which is somewhat of a complication. We carried out a detailed design study on this reactor in the United Kingdom and have decided not to proceed with it.

The Oak Ridge homogeneous aqueous 10-MW. reactor experiment was also described. In this reactor a fluid fuel of uranyl sulphate is contained in a zircalloy core vessel. This is surrounded by a blanket containing a slurry of thorium oxide which captures escaping neutrons and so gives the reactor a breeding potential. Two difficulties have occurred in this reactor. First, corrosion of the wall of the core vessel led to a leakage from core to blanket, so the reactor has at present to operate as a one-zone system. Secondly, there are problems concerned with the stability of the liquid fuel. The future of this reactor system will depend on the results of the experimental programme.

The fast reactor constitutes the fourth class of reactor experiments. So far, only experience on the American 1-MW. fast reactor has been reported. The experiment showed that instabilities occurred due to the geometry of the core fuel rods. This has now been redesigned and the difficulty eliminated. 60-MW. reactor experiments are due to be commissioned in the United Kingdom in 1959 and in the United States in 1960, and a 5-MW. reactor experiment is just going into operation in the U.S.S.R.

Fast reactors have a core of very small size and a corresponding very high rating. For this reason their capital costs should be low. On the other hand, the fact of a large rating produces severe technological problems, and only experience with the reactor experiment will show whether they can be solved. Fuel costs should in principle be low, since they would be fuelled by plutonium from second-generation reactors, presumably at the 'civil price' of about £5 per gm. The reactor should have a breeding factor of at least 1·5 and should turn over the fuel in about 1,000 days. The fuel costs will, however, be dominated by the number of times it is necessary to re-process the fuel during its life, and the cost of making the re-processed fuel into new fuel elements. To minimize these costs, the United States and the United Kingdom are developing the so-called pyro-metallurgical processing system, in which the fuel is melted and the unwanted fission products skimmed off, leaving behind some fission products which, when alloyed with plutonium, have been shown to have good stability to radiation. Until we know more about re-cycling costs, the economic future of fast reactors will remain obscure.

The technical feasibility of the nuclear propulsion of shipping has been abundantly demonstrated by the voyages of the U.S. submarine *Nautilus*, culminating in the remarkable voyage underneath the polar ice cap. The pressurized-water reactor used to develop steam for its propulsion has proved to be highly reliable. We heard at Geneva of the first approaches to commercial nuclear propulsion. The U.S. *Savannah*, a combined passenger-cargo ship coming into commission in 1960, will use a pressurized-water reactor developing 22,000 shaft horse-power. The pressurized-water propulsion unit seems likely to achieve fuel costs based on American prices about equal to those for oil fuel. Present capital costs are, however, three to four times higher than conventional capital costs, and a drastic reduction of these costs is necessary before parity with conventional propulsion is achieved. American engineers expect to build a nuclear tanker using a boiling-water reactor for propulsion by 1962. Since this type of reactor appears to have lower capital costs than the pressurized-water reactor, this should help to bridge the gap, though operating costs will still be well above conventional costs. It seems likely that we shall have to wait five years or more before we shall know whether truly commercial nuclear propulsion is a feasibility. However, there is one immediate application which would be impossible without nuclear power. The opening up of the 6,000-mile seaway north of the U.S.S.R. has had to wait for the practically unlimited endurance of the nuclear propulsion unit. The ice-breaker *Lenin*, which is due to be commissioned in 1959, will have three pressurized-water reactors installed, and two of these will provide 44,000 shaft horse-power for propulsion.

In contrast with the hopeful outlook for marine applications, commercial nuclear aircraft propulsion seems much further away.

EFFECTS OF WEATHER ON PLANT BEHAVIOUR

By Prof. J. P. HUDSON

Department of Horticulture, University of Nottingham School of Agriculture,
Sutton Bonington

CROP yields vary enormously from year to year and from farm to farm, but record crops, produced by the best managers in exceptionally favourable seasons, show how far yields usually fall below the full cropping capacity of the varieties which are at present available. One of the challenges in agronomy is to show how average yields could be increased. Since 'the weather' plays such an important part in determining the behaviour of plants, a more precise knowledge of the effects of environmental factors would be extremely useful in agriculture. In the first place, knowledge of varietal preferences would make it easier to select the variety most likely to yield heavily in any particular site, provided sufficient meteorological data were available to enable the pattern of probable weather conditions to be forecast. Thus the critical matching of variety to district, on which successful agriculture largely depends, would be placed on a firmer footing than by the traditional and time-consuming method of trial and error.

Another advantage of a fuller knowledge of response to environment is that, once the plant's requirements are known, it is sometimes practicable to exercise a degree of control over the environment itself, to provide conditions which are more nearly optimal for growth. An obvious example is the control of soil moisture and soil salinity, by the complementary techniques of irrigation and drainage, which now make it possible for crops to be grown on some two hundred million acres of land throughout the world which could not otherwise be used for agriculture. Less spectacular, though still useful, methods of environmental control on an agricultural scale are the reduction of air speeds by the use of windbreaks, and the reduction of light intensity by the use of shade trees in the production of some plantation crops. In horticulture, the grower often goes much further by using devices like cloches, frames and heated glasshouses which change such factors as temperature, wind speed and, to a lesser extent, light.

Much research is now being done on the effects of environmental factors on plant behaviour[1,2] and the possibilities of controlling these factors in crop production, but the position is frustrating. Apart from the control of water, and reduction of wind and light intensity, there seems to be little hope of affecting the other physical factors of the environment on a field scale. This is particularly the case with the two important factors of temperature and day-length, both of which have profound effects on the behaviour of many crop plants, and it is difficult to see how control of physical factors of the environment (apart from water) can make any substantial contribution to increasing yields of the major food crops in the immediate future. This is an unwelcome conclusion to those who are working on the agronomical uses of environmental control, but one which must nevertheless be accepted.

However, there is another possible approach. If it is impracticable to affect plant behaviour in the field by altering the nature of its environment, might it not be possible to alter the plant's responses to the natural environment ? For example, the use of a chemical treatment to affect the responses of a plant to temperature or day-length would be a much more elegant device than to try to alter those weather factors on a field scale. The results of some recent experiments suggest that this approach is worth considering.

The work has mainly been done on the raspberry (*Rubus idaeus* L.), which is not itself of much importance in world cropping, but was chosen because of its great convenience as an experimental plant. The pattern of the work has been, first, to study the behaviour of the species in the field, in order to distinguish between successive phases in the life-cycle, with particular emphasis on the behaviour of the stem apices. Next, plants have been grown in

Fig. 1. Diagram showing the phases of development of a raspberry shoot growing in a temperate climate, and the behaviour of the apical meristem(s) characteristic of each phase

controlled environments (growth rooms), to ascertain which types of 'weather' (that is, which levels of temperature, day-length and/or light intensity) cause the shoots to pass from one phase of development to the next. Thirdly, plants have been grown in environments which represented marginal weather conditions, where shoots are just 'held' in one phase and prevented from progressing to the next, and the shoots have then been treated with chemical stimulants to see whether they could be induced to pass to the next phase in weather conditions which would normally prevent that development from occurring.

The raspberry plant lends itself to such an investigation since suckers which arise from adventitious buds on the perennial root systems have life-cycles which can be divided into a number of discrete phases, in each of which the apices behave in different ways (Fig. 1). Under natural weather conditions in a temperate climate, leaf initials are laid down in the subterranean bud in phase 1, internodes elongate to carry the apex to the soil surface in phase 2, while leaves expand in phase 3, but internodes cease to elongate, and a rosette of leaves is formed. Thus, in the first three phases the three major phenomena of vegetative apices, namely, leaf initiation, internode elongation and leaf expansion, are each dominant in turn. The shoot then becomes dormant through the first winter, in phase 4, while in phase 5, which starts in the spring, leaf initiation, leaf expansion and internode elongation occur simultaneously. In phase 6, which occurs in the late summer or autumn in temperate climates, the shoot apex produces a rosette of leaves (and occasionally flower initials in some varieties), while the apices in most of the axillary buds change from the vegetative to flowering condition, until the shoot again becomes apparently dormant in phase 7. During this phase the condition of dormancy is broken by winter cold, but elongation does not start until the spring, when the axillary buds produce short lateral shoots, which bear leaves, flowers and, finally, fruits (phase 8). The cycle is completed in phase 9, when most of the shoot dies after fruiting, except for a short length at the base, near ground-level, from which a replacement shoot has meanwhile grown, to repeat the phases and continue the cycle of annual fruiting in the following year.

The phases of growth thus provide meristems in the following series of different conditions, and it is because of this succession, and the occurrence of phases in which meristematic activities are separable, that the species is of such interest :

	Phase
Vegetative apex:	
Emphasis on leaf initiation	1
Emphasis on internode elongation	2
Emphasis on leaf expansion	3
Dormant	4
Initiation, elongation and expansion occur simultaneously	5
Flowering apex :	
Flower initiation	6
Breaking of dormancy	7
Flower expansion to fruiting	8
Senescence and death	9

Since these phases are observed to occur with great regularity at particular seasons of the year in temperate climates, it was assumed that the progression from phase to phase was mainly the result of seasonal changes in the environment, and this aspect has been investigated further. My colleague, Dr. I. H. Williams, has elucidated the main effects of environment on development of the raspberry plant in a series of elegant experiments in four simple growth rooms where temperature, day-length and light intensity were controlled[3,4]. Williams has shown that differences in the behaviour of the apical meristem are largely brought about by changes in temperature and day-length, but there is an additional factor, in some phases, of 'ripeness to proceed' to the next phase, since it seems necessary for shoots to remain for a minimum period in some phases before they can enter upon the next even though

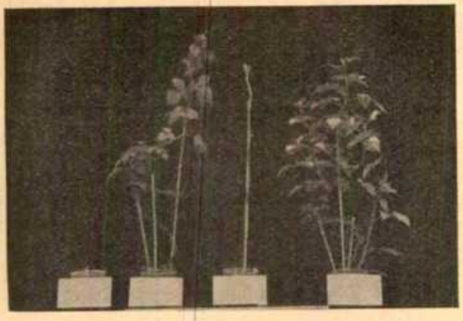

Fig. 2. Raspberry plants, all 32 weeks old, showing the effects of environmental factors on behaviour. Plants subjected to various combinations of 'summer', 'autumn' and 'winter' conditions in growth rooms show (left to right) a plant maintained in the rosette condition; one which has made continuous growth and is now 7 ft. high; a shoot in the winter dormant phase; and a plant with 'second-year' fruiting laterals in flower (left) and a new basal replacement shoot (right)

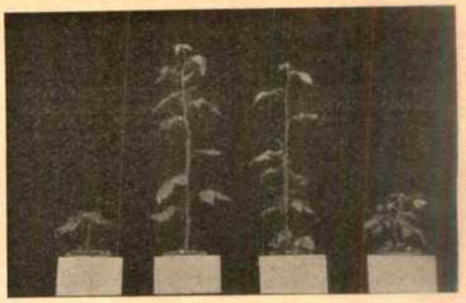

Fig. 4. Raspberry plants after 16 weeks in a growth room at 10° C. and 8 hr. day. Left to right: control plant with terminal rosette of leaves; plant treated with 1 μgm. gibberellic acid weekly from the outset; treated 1 μgm. weekly after rosette began to form; treated 1 μgm. weekly after rosette was fully formed. The shoot has continued to grow in the second and third plants, and recommenced growth from the rosette in the fourth

environmental conditions are conducive to that move.

Williams has also shown that the raspberry shoot can be maintained in some of the phases for far longer than the normal period, but that successive phases can also be telescoped by moving plants from one environment to another as soon as they are ripe for the next phase. Indeed, he has been able to reduce the time spent in each phase to such an extent that ripe fruits have been produced in several experiments little more than six months after the shoots had been initiated as buds on raspberry roots, thus reducing to a quarter the time which the complete cycle normally takes in Nature (Fig. 2).

It is thus quite feasible to affect the behaviour of this species by altering the nature of its physical environment, but work is now concentrating on methods of inducing shoots to pass to the next phase without changing the environment. The rosetted shoot (phase 3) has been chosen for this work, since it is at that time 'ripe to proceed' but is prevented from growing into a vigorously elongating leafy shoot by adverse weather conditions, which normally induce a period of dormancy in temperate climates. In most of the experiments elongating plants, grown at 18° C. and 12 hr. days, have been put into an environment with a lower temperature (10° C.) and shorter days (8 hr.), under which conditions they will normally form terminal rosettes of leaves within two or three weeks and thereafter remain in the rosetted condition for many months, slowly unfolding new leaves but with no elongation of the internodes (Fig. 3). Various chemicals have been applied to the stem apices, with outstanding results from the use of gibberellic acid, as might be expected from the effects which this remarkable growth-regulating compound has been shown to have on other species[5]. If elongating plants are put into this environment and are immediately given weekly treatments of 1–2 μgm. of gibberellic acid per plant, applied to the tip of the shoots with a micropipette, they continue to elongate steadily, unfolding new leaves (Fig. 4). On the other hand, if plants are allowed to form rosettes and are then given similar treatment they will recommence to elongate at once (Fig. 5). If the applications cease, the effect of the gibberellic acid wears off within a few weeks and the shoot once more rosettes, while re-introduction of the treatment a few weeks later causes elongation to recommence, with further leaf expansion, and so on. Thus, weekly applications of gibberellic acid at a low concentration will prevent raspberry shoots from rosetting, or will cause rosetted shoots to recommence elongation, under environmental conditions which would normally induce rosetting and maintain shoots indefinitely

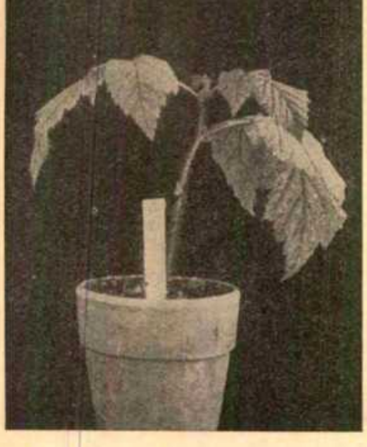

Fig. 3. Raspberry shoot showing a terminal rosette of leaves induced by putting a rapidly growing plant into a temperature of 10° C. and day-length of 8 hr.

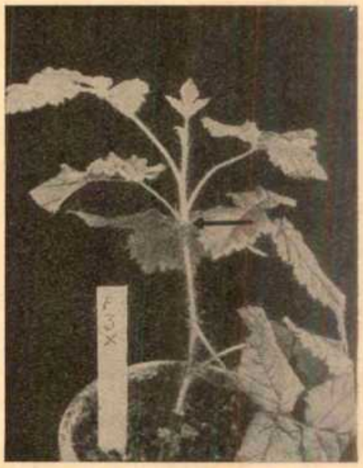

Fig. 5. Shoot recommencing to elongate from a terminal rosette (indicated by arrow) after being treated with gibberellic acid in an environment which would normally maintain the plant in the rosetted condition

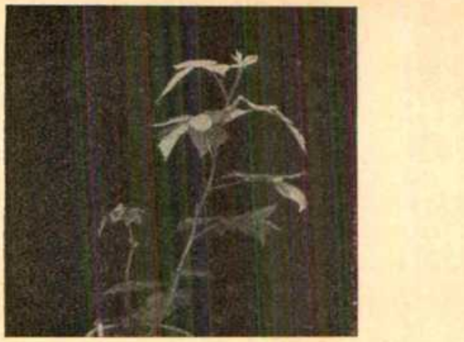

Fig. 6. Plant grown for six months at 10° C. and 8-hr. day. After forming a terminal rosette the original shoot (left) was treated with gibberellic acid, which caused it to recommence elongating and at the same time stimulated a basal shoot to grow (right) although that shoot was not treated at any time. When treatment of the left-hand shoot ceased after a few weeks it formed a new terminal rosette but the new shoot continued to elongate without rosetting

in that condition. Treatment with gibberellic acid, particularly after rosetting, also has the effect of stimulating the basal bud into growth, even though no acid is at any time applied to that bud or shoot, and there is a curious tendency for the new basal shoot to continue to elongate even after treatment with gibberellic acid has ceased and the original shoot has reverted to the rosetted condition (Fig. 6).

Heavier applications of gibberellic acid (for example, a single treatment with 200 μgm.) cause very rapid and abnormal elongation both of the rosetted apex and of the basal bud, which would not normally elongate until the following year, and the effects of such a single application persist for at least three months.

The importance of these results is that treatment with gibberellic acid changes the reaction of the plant to its environment, in this case causing a shoot to grow (that is, increase in length and leaf area) under weather conditions which would normally prevent it from elongating. By the use of appropriate dosages the growth made under the stimulus of gibberellic acid is quite normal and healthy.

Although the work on raspberry has little apparent application to general crop husbandry, it is not difficult to see the significance of these results. For various reasons such as risk of late frost or technical difficulties of cultivation, it is often necessary to delay the sowing or planting of crops, which make slow growth at first and may still be small when optimal growing conditions occur later in the season[6]. Earlier sowings may be useless in practice, since the young plants may fail to make appreciable growth under sub-optimal conditions of low temperatures or short days. However, if at this stage growth could be stimulated by chemical treatment under marginal weather conditions, but without causing the plant to initiate flower primordia, a larger plant might be produced by the beginning of the growing season, capable of taking full advantage of seasonal improvements in the weather. Crops might then make more total growth or might ripen earlier, or both.

The word 'marginal' is stressed. There is likely to be little profit in forcing plants to grow under dangerously sub-optimal conditions, and there might even be a risk of losing the crop altogether ; but the careful control of plant behaviour in response to certain marginal weather conditions might offer a technique of considerable practical value in agriculture, enabling the farmer for the first time to break the grip of the weather on his crops. The work will continue in this Department with raspberries and a few other species, but the purpose of this article is to suggest that it might be worth while to make similar investigations on the major world crop species in centres where facilities exist for that type of work.

I am grateful to my colleague, Miss J. M. Cook, for the use of some unpublished results of her experimental contribution to this work.

STRUCTURE AND REACTIONS IN ORGANIC CHEMISTRY

THE KEKULÉ SYMPOSIUM

A SYMPOSIUM on Theoretical Organic Chemistry was held in London during September 15–17 in celebration of the centenary of the discovery by Kekulé of the quadrivalency of carbon. Organized by the Chemical Society on behalf of the Organic Chemistry Section of the International Union of Pure and Applied Chemistry, the meetings were devoted to invited lectures and papers on chemical binding and structure, nucleophilic reactions, and electrophilic and homolytic reactions. The proceedings will be published in full.

It is probably true to say that no single paper has had so fundamental and far-reaching an influence on the development of organic chemistry as has Kekulé's paper of 1858 on "The Constitution and Metamorphosis of Chemical Compounds and the Chemical Nature of Carbon" (*Annalen der Chemie*, **106**, 129 ; 1858). It was in this paper that Kekulé clearly recognized that carbon is tetravalent and that carbon atoms can link together. These two concepts produced order out of chaos, led to the confirmation of the principle of homology, to the idea of closed rings and, in 1865, to the structure of benzene itself. Modern structural organic chemistry had begun, and the decades that followed saw the very rapid development of the subject which, with advancing years, included natural products and synthetic compounds of greater and greater complexity within its understanding. It was fitting, too, that this symposium should be held in London, because in 1854 Kekulé was appointed as private assistant to J. Stenhouse at St. Bartholomew's Hospital, and it was while travelling on the upper deck of a Clapham omnibus on the return journey from a visit to Hugo Müller at Islington that he first conceived the basis of his now famous *Strukturtheorie*.

The symposium was formally opened by Prof. H. J. Emeléus (Cambridge), the president of the Chemical Society. Each of the three days opened with a lecture, which was followed by the reading of five papers. Sir Christopher Ingold (London), Prof. W. Doering (Yale) and Prof. R. Huisgen (Munich) acted as chairmen.

The symposium opened with a lecture by Prof. L. Pauling (Pasadena) on the nature of the double bond and of conjugated and aromatic molecules. He pointed out that, although the nature of the single bond is now well understood, there still remains some doubt about the best description of multiple bonds and of the structures of molecules in which these bonds are considered to play a part. Of the two ways of describing the double bond—first, as composed of a σ- and a π-bond, and secondly, as composed of two equivalent 'bent bonds', the second was preferred. "Bent bonds", it was maintained, "are best". The two descriptions are equivalent in the approximation in which the bond orbitals are *sp*-hybrids, but the inclusion of contributions from *d*, *f*, etc., orbitals to the bond orbitals results in concentration of the orbitals in the direction of the bond, and causes the two descriptions to differ significantly. In these circumstances, the 'bent bond' description was shown to afford superior interpretations of the observed magnitude of potential barriers to rotation about certain single bonds adjacent to multiple bonds, of the ratios between single, double and triple bond-lengths, and of observed bond-angles. Some implications of the 'bent bond' concept in considerations of the structure of aromatic compounds were also discussed.

A comparison of the results of the resonance and molecular-orbital theories when applied to the ground states of some π-electron systems was given by Prof. H. C. Longuet-Higgins (Cambridge). It was shown that the molecular-orbital theory is to be preferred in the treatment of molecules such as *cyclo*butadiene and diphenylene, containing unsaturated rings in which the number of π-electrons is not of the form $(4n + 2)$. The use of localization energies for predicting the reactivities of molecules in both heterolytic and homolytic reactions was also illustrated. Further work on the theory of aromatic character was described by Prof. D. P. Craig (London), in which the possibilities of π-electron delocalization of orbitals other than $p\pi$, such as $d\pi$ and $f\pi$, were considered. In this wider framework aromaticity can be of two distinct kinds. Apart from the normal, or 'homomorphic' aromaticity, which is characterized by the prime role of the aromatic sextet, a second kind, called 'heteromorphic' aromaticity, is expected to occur in cyclic systems of alternating $p\pi$- and $d\pi$-orbitals, and should show no special preference for a sextet over an octet. Some features of the six- and eight-membered cyclic phosphonitrilic halides are compatible with delocalization of this type, and there are indications of the wider occurrence of this kind of aromaticity. The problems involved in the synthesis of new structural types possessing aromatic character were discussed by Prof. W. Doering (Yale). The structures discussed included the tropylium ion $C_7H_7^+$, and its relatives, tropone and tropolone. Among neutral molecules, in the five-membered series fulvene, C_6H_6, has recently been obtained, and also probably fulvalene, $C_{10}H_8$, by an arduous removal of four hydrogen atoms from two molecules of *cyclo*pentadiene. In the seven-membered series heptafulvene, C_8H_8, has been obtained in solution as an unstable, deep-red compound, and heptafulvalene, $C_{14}H_{12}$, has been obtained as a violet-red crystalline substance.

Attempts to provide quantitative experimental results to support quantum-mechanical calculations on conjugated systems by Kistiakowsky's classic method of measurement of heats of hydrogenation were described by Prof. R. B. Turner (Houston). In the more recent experiments described, it has been possible to apply corrections for steric strain energies to the measured total stabilization energies. Such corrections were shown in some instances to be large and important. In the last paper of the first day, Prof. C. A. Coulson (Oxford) discussed the influence of steric deformation and consequent departures from exact planarity on the π-electron structure of conjugated and aromatic molecules. The several distinct situations which can arise, namely, rotation about a formally single bond, as in diphenyl, large polynuclear over-crowded hydrocarbons like dibenzophenanthrene, where the strain is distributed over the whole molecule, phenanthrene-type distortions in which hydrogen atoms are displaced out of the plane, and buckled rings such as hexachlorobenzene, were considered separately.

The second day of the symposium was opened by Sir Christopher Ingold (London), who delivered a lecture on "Nucleophilic Octahedral Substitution". The displacement of the ligand X as an anion from various cobaltic ions of the form $(\mathrm{Co\ en}_2AX)^+$ is typical of this class of reaction, in which the regular space-figure involved is an octahedron. The kinetic characteristics of these reactions point to the dominance of two mechanisms, analogous to the known organic-chemical mechanisms S_N1 and S_N2. The analogy extends fairly closely to the effects of substituent groups and of the nucleophilic capacity of the reagent on reactions by both mechanisms. The interpretation of the stereochemical results of these substitution reactions is complicated by the circumstance that the geometrical correlation between experimental result and molecular cause is less clear-cut in octahedral than in tetrahedral substitution. It appears that neither S_N1- nor S_N2-type octahedral substitutions by anions are stereochemically specific, although the latter show evidence of orientation, by the preserved ligands, caused principally by conjugative electron-displacement. However, octahedral substitutions of chloride ion by neutral water appear to proceed uniformly without stereochemical change. The theoretical implications of these findings and, in particular, of the differences between the neutral and anionic reagents, were discussed in detail.

Prof. J. D. Roberts (Pasadena) discussed the results of a kinetic investigation into the hydrolysis of diaryliodonium salts to phenols and aryl iodides. The reaction was studied under conditions likely to give rise to an S_N1 mechanism, since under these conditions phenyl cations might be expected to be produced. However, the rather unexpected results which were obtained on the effects of substituent groups on the distribution of products, and the catalytic effects of oxygen, acids and copper salts were taken as an indication that the complete reaction, which can be described as a nucleophilic substitution, involves the intermediate formation of solvent-caged free radicals. Recent research on the phenomena of fragmentation in solvolytic reactions was described by Prof. C. A. Grob (Basle). The heterolysis of a bond to an electron-acquiring group X in a system a–b–c–d–X may lead to the heterolysis of the bond between b and c, resulting in fragmentation (β-cleavage) of the molecule, as well as to the well-understood processes of substitution, elimination and rearrangement :

$$a - b - c - d - X \rightarrow a \rightarrow b^{+} + c = d + X^{-}$$

This can occur if a is an electron-donating group, and is particularly prevalent in γ-amino-halides, where a is $-NR_2$. Two unimolecular mechanisms for the fragmentation have been found to be operative, namely, a one-step process in which ionization of X and cleavage of the C_β—C_γ bond are synchronous, and a two-step mechanism in which the rate-determining ionization is followed by a faster product-determining step, which can lead to fragmentation or to other processes.

A review of recent progress in conformational analysis was given by Prof. D. H. R. Barton (London). The subjects discussed included the rearrangement of diaxial products of addition reactions to the *cyclo*hexene system to the corresponding diequatorial isomers, which was illustrated by new rearrangement reactions of halohydrin esters. After a review, in conformational terms, of the behaviour of carbanions, Prof. Barton concluded his paper with a discussion of long-range group effects in large saturated molecules, such as steroid and other systems. It was concluded that these effects are transmitted by the successive distortion of valence angles. The effect is referred to as 'conformational transmission'. The S_N2 mechanism of substitution at aromatic and other unsaturated centres was discussed in a paper by Dr. J. F. Bunnett (Providence). It was shown that in contrast to the synchronous S_N2 mechanism of substitution at a saturated carbon atom, the S_N2 mechanism in these examples involves the formation of metastable intermediate complexes. Often the bond to the incoming group is completed before the bond to the outgoing group starts to be broken. It is possible that the strictly synchronous S_N2 mechanism is unique for displacements at saturated carbon. The role of 'benzyne' intermediates in rearrangements observed during nucleophilic aromatic substitutions with alkali amides or organolithium compounds was reviewed by Prof. R. Huisgen (Munich). Recent investigations were described which establish the mechanism more firmly and resolve some of the discrepancies attendant upon it.

Prof. M. J. S. Dewar (London) opened the last day of the symposium with a lecture on "Rearrangements in Aromatic Compounds". These rearrangements were classified and their possible mechanisms, including the intramolecular mechanism involving the formation of π-complexes, were discussed. New experimental work on the rearrangements of N-bromoacylanilide derivatives, and the acid-catalysed rearrangements of alkyl aryl ethers, was described. Both these rearrangements appear to be intermolecular. The mechanism of the benzidine and related rearrangements was discussed in the light of known experimental data, and the intramolecular mechanism previously suggested by Prof. Dewar was shown to be not inconsistent with the recently discovered dependence of the rate of rearrangement on the square of the concentration of the acid catalyst.

Researches on the mechanism of nitration were reviewed by Prof. E. D. Hughes (London). Although the mechanism of nitration via the nitronium ion is very common, the paper included a discussion of nitration via nitrosation, and C-nitration via N-nitration and rearrangement. Work on O-nitration, which also proceeds via the nitronium ion, was discussed. Some recent studies of reactivity and orientation in aromatic halogen substitution reactions were described by Dr. P. B. D. de la Mare (London). Halogenation can take place either directly, by the molecular reagent, or with the intermediate formation of chlorine or bromine cations, or their hydrated forms. The conclusion that the inductive effects of substituent groups are less important in determining orientation in substitution by molecular than by charged species was reached from a consideration of recent work on halogenation, and was discussed in terms of the transition states for the two modes of substitution.

Recent evidence for the operation of quasi-heterolytic mechanisms for reactions in the gas phase was presented by Dr. A. Maccoll (London). The reactions considered, for which such mechanisms appear to be correct, were the unimolecular dehydrohalogenation of alkyl halides and olefin elimination from esters. The first group shows close similarities to the S_N1 and $E1$, and the second to the $E2$, mechanisms for reactions in solution. The possibility of acid catalysis in the gas phase was discussed with reference to the elimination of olefins from alcohols catalysed by hydrogen halides. The remaining two papers dealt with homolytic reactions. Prof. D. H. Hey (London) described recent work on reactions of aroyl peroxides with naphthalene. The formation of arylnaphthalenes, naphthyl esters and dinaphthyls, and the proportions in which the various isomers of these substances were formed, were rationalized in terms of the various substitution and hydrogen-abstraction reactions which may occur with radicals of different polar and steric requirements. Recent measurements of the methyl (alkyl) affinities of various aromatic compounds and olefins were presented and discussed by Prof. M. Szwarc (Syracuse). The relationship between the experimental results and theoretical calculations of localization energies was shown to be consistent with a model of the transition state for attack by alkyl radicals in which the repulsion between the radical and the molecule and the attraction between the same radical and the 'residual' molecule (that is, a hypothetical molecule in which an electron is localized on one of the carbon centres) are balanced.

On the evening of September 15 those attending the symposium were invited by the University of London to a reception by the Vice-Chancellor (Dr. C. F. Harris) at the Senate House. On the following evening the Kekulé Symposium dinner was held at the Connaught Rooms, at which the speakers were Prof. H. J. Emeléus (president of the Chemical Society), Prof. P. E. Verkade (president of the Section of Organic Chemistry of the International Union of Pure and Applied Chemistry) and Prof. R. Huisgen.

G. H. WILLIAMS

OBITUARIES

Prof. K. S. Lashley, For.Mem.R.S.

KARL SPENCER LASHLEY was born in West Virginia on June 7, 1890. He died in Paris in August 1958.

Whatever may turn out to be the correct detailed story of nerve conduction and the localization of mental functions in the brain, it is safe to say that Lashley's work will always stand distinguished for the brilliance of his experimental attack, for the originality and sweep of his ideas, and for the incisiveness and clarity of his exposition.

Lashley received his scientific training, about equally in zoology and in psychology, at the Universities of West Virginia, Pittsburgh and Johns Hopkins. He became a professor of psychology first in the University of Minnesota and then at Chicago. In 1937 he was appointed research professor of neurophysiology at Harvard, and five years later he also became director of the Yerkes Laboratories of Primate Biology at Grange Park, Florida. It was in Florida, in his home there, working among his chimpanzees, with his carefully chosen band of students, and often piloting his small sailing boat, mostly alone in coastal waters, that he spent, probably, the happiest years of his life.

Some of Lashley's early work was carried out in conjunction first with H. S. Jennings, and later with the behaviourist, J. B. Watson. But he never, all his life, for long allowed himself to stay tied to anybody else, or to theories other than his own. Perhaps it was their unconventional character, and the fact that they were rebelling against respectable and established opinions of their day, which attracted him in turn to behaviourism, to Pavlovian conditioned reflex theory; and then, by what seemed rather like a complete somersault, to *Gestalt* psychology, and even to some of the more romantic aspects of Freudism. All of these had some influence with him; none of them carried him away.

From 1912, when he published his first paper—on visual discrimination of size and form in the albino rat—to the middle 1920's, he was busy with many and varied experimental investigations in animal behaviour. These moved more and more definitely towards what he called "studies of cerebral function in learning". In 1929 he published his famous book "Brain Mechanisms and Intelligence", and this was very quickly recognized as of outstanding importance. Nearly everybody who writes now of this volume directs attention to Lashley's two principles of brain activity, which he called "Equipotentiality" and "Mass Action". Taken together and in a broad sense, these principles, and particularly the abundant, detailed and original evidence upon which they were based, expressed and demonstrated the view that there could be considerable loss or injury to brain tissues and still the behaviour functions subserved by the areas concerned could be carried on, though sometimes in ways new and different compared with those which had been learned. What particularly marked Lashley's neurophysiological approach was its loyalty, at the same time, to the highest and most exact standards of behaviour experimentation. Plenty of people have shown that it is easy to be scientifically exacting on one side, and little but dogmatic on the other; Lashley accepted and used the same rigour of research on both.

Until he moved to Florida and the chimpanzee colony, most of Lashley's experimental work had been carried out with rats. But with the opportunities which he now had, he began to devote more attention to studies of the neurophysiological foundations of some of the higher and more complex mental functions. In a broad sense, his views about the areal and patterned character of brain activities remained unchanged. He continued to publish a number of splendid papers, and he inspired notable experimental work by his students. But he ran into a period of prolonged ill-health. In the summer of this year he seemed to be better, and he set out upon one more journey to Great Britain and to France. He had been elected a Foreign Member of the Royal Society in 1951. On July 28 he signed the Charter book of the Society, and then continued his planned trip to France. There, in Paris, about a fortnight later, he died.

Lashley, superbly intelligent himself, liked people to be, in his judgment, intelligent. He very quickly made up his mind about this, and anybody who met him, though maybe only for a short time, and was accepted by him as up to the mark, could never forget his brilliant, rather wayward, and most lively habit of mind. Though he was a fine and patient experimenter, he was no laboratory recluse. High among more general interests were music—he was good with a violin—and sailing. Sometimes he said that he would have liked best of all to sail lonely voyages across the widest seas in some small boat. When he came to Europe he always preferred, if he could do so, to travel in a little tramp steamer; he disdained the luxury liner. Life to him was an adventure, a continuing opportunity for original exploration, whether in action or by thought, and if it could be very clear that the responsibility for whatever he found was wholly his own, that was all the better.

F. C. BARTLETT

The Rev. T. N. Burke-Gaffney, S.J.

WITH the death of Thomas Noel Burke-Gaffney on September 14, Australian seismology has suffered an almost irreplaceable loss.

Father Burke-Gaffney became director of the Riverview College Observatory in 1952 when the former director, Father D. J. K. O'Connell, was appointed director of the Vatican Astronomical Observatory. He occupied the post with distinction, and more than maintained the reputation which Riverview has held for fifty years as one of the world's first-class seismological observatories.

He was that rare type of seismologist to whom the records of each earthquake take on the form of a distinct personality. Through this faculty, he developed an insight into the reading of seismic records the like of which we may not see again in Australia. He was devoted to his work, and few outside the ranks of seismologists in Sydney and a small number of his close colleagues know of the extent to which he helped, beyond his strength, young seismologists in many parts of Australia to an understanding of the intricacies of seismic recording.

He played a valued part in Australia's International Geophysical Year work as convener of the

National Subcommittee on Seismology, and was for several years a member of the Council of the Royal Society of New South Wales. In these and related offices he gave of his best.

His published work includes seven papers on seismology, the last of which appeared in the *Australian Journal of Physics* shortly after his death. The papers were concerned with the seismicity of Australia, the problem of detecting *S* waves in the Earth's inner core, special phases from New Zealand earthquakes, and seismic aspects of nuclear explosions. The last work has attracted world-wide attention.

Father Burke-Gaffney was born in Dublin on December 26, 1893, and entered the Jesuit order in 1913. He took up residence in Australia in 1928 as senior science master at St. Ignatius's College, Riverview, Sydney, and in 1946 became assistant director of the College Observatory. He lived austerely, and was one of Australia's most unassuming scientists and a man of quiet, gentle dignity. Few outside his College friends and his seismological colleagues got to know him well; but those of us who did, knew him as a charming liberal-minded man graced with a delightful humour and who dedicated himself to his work.

K. E. BULLEN

NEWS and VIEWS

Nobel Prize for Medicine and Physiology: Prof. J. Lederberg; Prof. G. W. Beadle and Dr. E. L. Tatum

THE recent award of the Nobel Prize for Medicine and Physiology for 1958 to Prof. Joshua Lederberg, and jointly to Prof. G. W. Beadle and Dr. E. L. Tatum, is a signal acknowledgment of the great advances which have been made in knowledge of the genetics of micro-organisms in recent years, and of the importance of this knowledge to an understanding of living processes in general.

The main contribution of Beadle, the geneticist, in collaboration with Tatum, the chemist, was to show first, in 1941, that mutations induced by irradiation in the mould *Neurospora crassa* resulted in inability to synthesize specific chemical nutrients which the organism needed for growth. Genetic crosses between the mutant and parental strains invariably showed that each mutant strain, having a single specific requirement, differed from the parental strain by alteration of only a single gene. Thus single genes appeared to control single biochemical reactions and, by inference, the formation of single enzymes. This first successful attempt to relate genetic and biochemical function experimentally gave birth to the stimulating 'one gene, one enzyme' hypothesis and initiated the expanding field of biochemical genetics. In further studies Beadle and Tatum traced the synthetic defects of some of their mutant strains to inability to perform various specific intermediate steps in the chain of processes leading to formation of such required end-products as amino-acids or vitamins of the B group. By wedding experiments with such mutants to inspired guess-work concerning presumptive precursors in biosynthesis they, and many subsequent workers, have built up a formidable mass of knowledge about intermediary metabolism.

Tatum (1944–46) extended these *Neurospora* studies to bacteria. As a result, a considerable stock of nutritionally defective mutant strains of *Escherichia coli* were developed. Lederberg, who was working with Tatum at this time, conceived the idea that these mutants might be used to provide a definitive test of the occurrence of sexuality in bacteria. The experiments were immediately successful and were first reported jointly by Lederberg and Tatum in 1946 in *Nature*. Subsequent studies by Lederberg proved the existence of a linear linkage between many of the genes of *Escherichia coli*, thus showing, for the first time, that bacteria are fundamentally similar to other types of cell in their genetic and biochemical constitution. These studies, which then appeared to S. E. Luria "to be among the most fundamental advances in the whole history of bacterial science", served as the starting point for many far-reaching discoveries in the field of bacterial genetics which Lederberg has ever since continued to fertilize with new ideas and techniques. In 1952, he and Dr. N. D. Zinder showed that certain bacterial viruses (bacteriophages) could act as vectors of small fragments of bacterial chromosome from one cell to another so that recombinant types arose: development of this discovery, especially by Dr. M. Demerec and his colleagues, has provided important new concepts about the fine structure and function of the gene. In 1953, Lederberg and his wife, Dr. Esther M. Lederberg, simultaneously with Dr. E. Wollman of the Pasteur Institute, Paris, first proved that the genetic material of a bacterial virus of low virulence might attach itself to a specific site on the bacterial chromosome and thereafter be propagated indefinitely among the progeny of the host cell as though it were part of its normal hereditary constitution. Lederberg and his wife also developed a simple but elegant technique, known as 'replica plating', which, in addition to its wide applicability as a laboratory tool, was used by them to demonstrate directly, for the first time, that bacterial mutations, such as resistance to certain antibiotics or viruses, arose spontaneously and not in response to environmental stimuli.

Royal Society: Medal Awards

THE following awards of medals have been made by the President and the Council of the Royal Society: *Copley Medal* to Prof. J. E. Littlewood, lately Rouse Ball professor of mathematics in the University of Cambridge, for his distinguished contributions to many branches of analysis, including Tauberian theory, the Riemann zeta function, and non-linear differential equations; *Rumford Medal* to Sir Thomas Merton, formerly professor of spectroscopy in the University of Oxford, for his distinguished researches in spectroscopy and optics; *Davy Medal* to Prof. R. G. W. Norrish, professor of physical chemistry in the University of Cambridge, for his distinguished work in chemical kinetics, especially in photochemistry; *Darwin Medal* to Sir Gavin de Beer, director of the British Museum (Natural History), for his distinguished contributions to evolutionary biology; *Sylvester Medal* to Prof. M. H. A. Newman, Fielden professor of mathematics in the University of Manchester, for his distinguished contributions to combinatory topology, Boolean algebras and mathematical logic; *Hughes Medal* to

Prof. E. N. da C. Andrade, emeritus professor of physics in the University of London, for his distinguished contributions to many branches of classical physics.

The Royal Society of Edinburgh

The following officers and members of Council were elected at a meeting of the Royal Society of Edinburgh, held on October 27: *President*, Prof. J. Norman Davidson; *Vice-Presidents*, Prof. A. C. Aitken, Dr. J. E. Richey, Prof. D. Whitteridge, A. W. Young, Prof. E. L. Hirst, Prof. J. R. Matthews; *General Secretary*, Prof. Norman Feather; *Secretaries to Ordinary Meetings*, Dr. A. W. Greenwood and Dr. Mowbray Ritchie; *Treasurer*, Dr. J. R. Peddie; *Curator of Library and Museum*, Dr. Douglas Guthrie; *Ordinary Members of Council*, Dr. J. A. Macdonald, Dr. Robert Schlapp, Dr. J. B. Tait, Prof. G. M. Wyburn, Prof. R. A. Rankin, Prof. A. E. Ritchie, Prof. W. M. Smart, Prof. V. C. Wynne-Edwards, Prof. E. G. Cullwick, Prof. G. Pontecorvo, Prof. M. M. Swann, Prof. T. S. Westoll.

Zoological Society of London: Dr. D. Morris

The Zoological Society of London has appointed a new curator of mammals, Dr. Desmond Morris, who will commence his duties on January 1, 1959. Dr. Morris graduated at the University of Birmingham and then moved to Oxford to study for a doctorate on animal behaviour under Dr. N. Tinbergen, and remained to expand his studies with several years of postdoctoral research. His work was mainly concerned with the analysis of aggressive, sexual, parental and social behaviour patterns in various vertebrate species. He published numerous papers on these subjects, including several monographs, in which attempts were made to unravel the whole social structure of particular species. Other papers dealt with modifications and extensions of certain behaviour concepts, such as displacement activities. His most important studies were in the field of animal communication, where he introduced the concept of 'typical intensity', and focused attention on the importance of autonomic signals in the evolution of animal language. Three years ago, Dr. Morris left Oxford to take up the post of head of the Granada Television and Film Unit at the Zoological Gardens, London, and has since devised and presented more than a hundred television programmes about animals. Working on these programmes inside the Zoo has given him wide experience of the Zoological Society's collection of mammals. This experience, combined with his knowledge of animal behaviour problems in general, will prove invaluable when he takes up his new appointment next January.

A New Higher Technological Award

The National Council for Technological Awards has announced that in order to encourage qualified men and women to undertake further study beyond the level of the diploma in technology (Dip.Tech.) and to carry out original investigations, it has decided to create a higher award. It is intended that this award shall be a mark of distinction granted to a student who has proved his ability by completing a substantial programme of work demanding the application of his knowledge to the solution of a problem of value to industry. The Council will establish a new college, to be known as the College of Technologists, and the new award will take the form of membership of this College (M.C.T.). To qualify for this award a student must undertake a programme of work to be carried out jointly in industry and at a technical college. This programme may be concerned with any technological aspect of industrial activity, such as research, development, design, production or market investigation. The Council believes that to carry out successfully post-diploma work of this character, students must remain in contact with industry or with commercial laboratories. A candidate must apply for registration to the College of Technologists through the technical college at which he will study. The programme offered should be related to the student's experience in industry and have the approval of his employer. It should be likely to result in a useful contribution to technological knowledge and require industrial experience and academic study extending over a substantial period; a three-year period of work is envisaged, provided a high proportion of a student's time can be devoted to it. The work must be supervised by a member of the staff of the technical college at which it is undertaken and by a staff member of the industrial organization concerned. The technical college concerned will be responsible for the examination of candidates, subject to any general arrangements, including the approval of external examiners, which may be prescribed by the College of Technologists.

Exchange of Scientific Information

Asked on November 5 about reciprocity between Great Britain and the United States of America and the U.S.S.R. for the exchange of scientific and educational and cultural information and personnel, Mr. Ian Harvey said there was complete reciprocity between Great Britain and the United States. The Soviet Government had refused a request from the British Government in April for talks on various aspects of freedom of information with a view of similar reciprocity between Britain and the U.S.S.R. Within a more limited sphere, however, reciprocal exchanges in the educational, cultural and scientific fields were arranged by the Soviet Relations Committee of the British Council, set up for this purpose in 1955 at the request of the British Government. The scale of these arrangements has increased in the past six months and reciprocal exchanges of scientific publications have recently been intensified.

Science Teachers and Laboratories

In the House of Commons on November 6, the Minister of Education, Mr. Geoffrey Lloyd, stated that in March 1957 the heads of schools reported that they had about 500 vacancies for graduate teachers of science and mathematics, and that about 400 posts were unsatisfactorily filled. In a written answer, he stated that no arrangement has been made by his Department with the Industrial Fund for the Advancement of Science Education in Schools. The latter directs its attention to the independent and direct grant schools, because responsibility for the maintained schools rests with the local education authorities and his Department. The capital cost of new science laboratories being provided each year at maintained schools is now about £2 million.

Nuclear Installations (Licensing and Insurance) Bill

The intention of the Nuclear Installations (Licensing and Insurance) Bill, which has recently been published, is to ensure that nuclear reactors on land are made effectively subject to control in the interests of safety and that their owners make adequate provision for the payment of compensation should the need arise. The Government's intention to introduce legislation on these lines was announced in the House of Commons on February 10 by the Parliamentary Secretary to the Minister of Power. The operation of a nuclear reactor will require a licence from the Minister of Power (in Scotland the Secretary of State), and every licensee will have to pay compensation for any damage to property or personal injury from radioactive contamination even if it is due to an unavoidable accident, except to the extent that the claimant has been guilty of contributory negligence. The licensee will be required to insure his liability or show that he has adequate liquid assets. The liability is limited to £5 million in respect of any one incident. In the highly unlikely event of an incident causing more than £5 million worth of damage, special measures would be needed, and claims will be dealt with as Parliament determines. Since certain types of injury from radiation may become apparent only after a long time, the Bill provides that damages may be claimed up to ten years after the incident concerned. The U.K. Atomic Energy Authority already has a similar liability to that proposed in the Bill but it is not limited in amount; the Bill contains provision to extend the Authority's present liability to cover nuclear fuel in the course of carriage. The insurance market has informed the Government that it is ready to provide the necessary cover. Questions about premiums are a matter for the insurance market and the owners of reactors.

European Nuclear Energy Agency

In a pamphlet, "European Nuclear Energy Agency—Structure and Functions—First Joint Undertakings" (pp. 12. Paris: Organization for European Economic Co-operation, 1958), the Organization for European Economic Co-operation has issued what is largely a popular and illustrated version of the first report of the Steering Committee for Nuclear Energy. There are included some accounts of the organization of the Agency and the way in which it seeks to co-ordinate European scientific and technical activity in this field and to provide an overall view of research and investment programmes in nuclear energy in Europe, as a step towards harmonizing these programmes and avoiding duplication. Some account is also given of the stage reached in the construction of the nuclear study centre at Mol, where the small-scale joint plant for treating fuels from different reactors is to be built, of the boiling water reactor built at Halden by the Norwegian Institute for Atomic Energy and other projects of Eurochemie. There is also a map showing nuclear installations in member countries and a brief bibliography.

Civil Service Commissioners: Report for 1957–58

The ninety-second annual report of the Civil Service Commissioners, covering the period April 1, 1957–March 31, 1958 (pp. 32. London: H.M. Stationery Office, 1958. 2*s.* net), again refers to difficulties in recruitment and failure to meet all requirements; in most of the main classes of the Civil Service there were more vacancies than suitable candidates. During the year, 111,702 candidates were dealt with, compared with 112,590 in the previous year, but the number of successful candidates rose from 11,606 to 13,057 and the quality of applicants for the administrative class improved. There were thirty-nine successful candidates for forty vacancies, and it appears that the measures taken in recent years to make the work of the administrative class better known to university students have yielded results. The shortage of young trained scientists continued to affect recruitment to the scientific officer grade and more than half the vacancies advertised remained unfilled, although in the senior scientific officer competition most of the vacancies declared by departments were filled. Sixteen candidates of high promise were offered fellowships as a result of the Research Fellowship Competition, and, as a new departure, information about the 1958 Fellowship Competition was sent to British nationals at present holding Canadian and United States Fellowships. About seventy were willing to attend interviews which took place in Ottawa and Washington. Only thirty-six out of sixty-five declared vacancies for patent examiners were filled, and there was a decrease in applicants for vacancies in the engineering and technical classes. Recruitment of candidates with good scientific and technical qualifications into the Factory Inspectorate remained difficult. The continued lack of well-qualified young entrants for the engineering posts causes concern as to the future leadership in this field.

National Science Foundation Grants for Undergraduate Research

The U.S. National Science Foundation has announced plans to make a limited number of grants to colleges, universities and non-profit-making research institutions to provide, on an experimental basis, opportunities for undergraduates reading for degrees in the physical, biological, mathematical and engineering sciences to participate in research projects conducted by experienced scientific investigators. This scheme may operate either during the academic year or during the summer. Approximately 1,000 undergraduates at about one hundred institutions in the United States will be able to participate in these laboratory and field programmes which will afford them an opportunity to become acquainted with the nature and methods of research in progressively more independent roles. The Foundation will provide grants up to a maximum of 400 hr. per student. Expendable supplies and secretarial and administrative expenses directly attributable to this student training will also receive support.

Talanta: a Journal of Analytical Chemistry

The first issue of a new journal, *Talanta* (1, Nos. 1/2; July 1958. Pp. 196. Published bimonthly. Subscription (including postage): 17 dollars a volume (Great Britain, 120*s.*); for subscribers certifying that the journal is for their own personal use, 15 dollars (Great Britain, 105*s.*). New York and London: Pergamon Press, 1958), has now been published, with Dr. C. L. Wilson, of the Queen's University, Belfast, as editor-in-chief, regional editors in the United States, Czechoslovakia and Japan, and an advisory board of chemists eminent in the field of analytical chemistry. The editors hope to expedite the publication of the results of research by publishing papers within three to four months of acceptance and short communications within thirty to sixty days. Papers can be submitted in English, French or German. The present double issue contains twenty-one research papers, followed by short communications, book reviews, notices and lists of books and papers received.

Forum

A NEW educational journal has recently been launched with the view of discussing new trends in education with the appropriate title of *Forum*, and under the joint editorship of two lecturers in education at the University of Leicester, R. Pedley and B. Simon. Particularly concerned with the efforts to abolish the tripartite system of education in England and Wales, the first issue contains details of the present stage of the London plan to reorganize its secondary education in a system of comprehensive schools. There is also an account of the early stages of the Leicestershire experiment to eliminate the 'eleven-plus' examination without bringing all children within a single comprehensive school. These will be followed in future issues by articles describing changes in other areas of Britain where some form of comprehensive education is taking place. The journal is also concerned with the efforts now being made in many junior schools to modify rigid streaming and with new developments in the secondary modern schools. There is also a symposium on "Science Teaching in the Nuclear Age" and an article by Dr. Robin Pedley assessing the educational programmes of the political parties. Provided that future issues of the journal will remain as free from political bias as the first, *Forum* should provide a valuable means of communicating new thoughts and developments in the realm of secondary education. Whether this courageous experiment can survive at its present price (3*s*. for single issues or 8*s*. 6*d*. for three issues in one year) must be a cause for concern. The journal is published from 71 Clarendon Park Road, Leicester.

Science in Six American States

A REPORT recently issued by the U.S. National Science Foundation, entitled "Scientific Activities in Six State Governments", summarizes the findings of a survey conducted in 1954 to determine expenditure and man-power involved in scientific activities in California, Connecticut, New Mexico, New York, North Carolina and Wisconsin. The study covered only State-supported activities, including research and development, collection of data, dissemination of scientific information, training of scientific man-power, and testing and standardization. Of the total expenditure of 68·9 million dollars reported, 57 million dollars were spent on research and development, and of the total 4,335 man-years, 3,831 were similarly devoted. Scientific activities in State universities and agricultural experimental stations accounted for just less than 70 per cent of the totals in both dollars and man-years. The proportion devoted to research and development was similar in all six States, and health, education, welfare, research development and public works accounted for 80 per cent of both funds and man-years. In all six States, the business, labour and vocational licensing agencies and the State universities tended to rely more heavily on Federal funds for their programmes of scientific activity than did other groups of agencies, and this is attributed directly to the high level of Federal participation in the employment security functions of State governments. Some reference is made to the character of State organization in the conduct of research and development, to interdepartmental machinery for co-ordinating programmes, as well as to the inter-State and Federal influence of such co-ordination.

Birds and Mammals of Canada

FOLLOWING many requests from visitors to the Museum, the Department of Northern Affairs and National Resources of the National Museum of Canada has published two attractive booklets describing many of the native birds and mammals. The first ("Quelques Oiseaux du Canada." Pp. 48. (14 planches.) Ottawa: Queen's Printer, 1957. 35 cents), written in French by W. E. Godfrey, describes the typical characteristics of a bird, the distribution and numbers of birds throughout Canada, song, territory and breeding cycles, migration routes, food and the relation of birds to man. This is supported by details of some of the better-known and less well-known birds of Canada. The second ("Canadian Mammals." Pp. 81. Ottawa: Queen's Printer, 1958. 50 cents), written in English by A. W. Cameron, describes most of the bigger mammals such as the harp seal, the finback, white whale and blackfish, as well as the smaller mammals like the cinereous shrew and the star-nosed mole. Each account includes details of the anatomy, ecology and breeding behaviours of the mammal as well as a clear and attractive black-and-white drawing by John Crosby. The birds have been similarly illustrated by the same artist.

Coastal Erosion

ONE of the principal preoccupations of students of coastal erosion is the way in which beach material moves under the influence of waves and currents. Until recently, it has not been possible to obtain direct evidence. In an article in the *Geographical Journal* (124, part 2, 210; June 1958) a method of marking pebbles with the radioactive isotope barium-140 – lanthanum-140 is described. It is possible, by searching the sea bed and beach with Geiger counters, to trace the movement of the marked pebbles. This has been done at Scolt Head, and the present paper, by C. Kidson, A. P. Carr and D. B. Smith, gives an account of its application to Orford Ness, the shingle spit at the mouth of the River Ore in Suffolk. During a period of six weeks a large number of contacts was obtained, and it was shown that beach material moves along shore under almost all conditions and in more than one direction. The direction of movement is principally determined by the winds prevailing at the time, and the general direction of longshore drift is that developed under the influence of the dominant wind. It was also shown that river mouths, even where flood and ebb tides are strong, do not form barriers to the movement of beach material.

Galactic Rotation

MORE than twenty years ago Plaskett and Pearce gave an authoritative discussion of the rotation of the galactic system, using material referring mostly to the northern section of the Milky Way and to distances less than one kiloparsec. During the past six years the lack of observations from the southern hemisphere has been remedied at the Radcliffe Observatory, Pretoria, where 350 velocities of early-type stars have been obtained. A new analysis of galactic rotation has been made by M. W. Feast and A. D. Thackeray, and their results have now been published (*Monthly*

Notices of the Royal Astronomical Society, 118, 125, 1958). Their work was based on a selection of the available data, including only the more distant stars, for which the velocities should show galactic rotation effects. The rotation is usually described by the Oort constant A; the value of A has been the subject of some controversy. Analysing their data in several ways, Feast and Thackeray obtain for A the mean value 17·5 ± 1·5 km./sec./kiloparsec. The new results do not support the lower values of A obtained in some earlier determinations. Two partly independent methods were used to derive a value of the distance from the Sun to the galactic centre; the most probable value is 8·9 kiloparsecs. A value of 0·5 for the ratio of the axes of the velocity ellipsoid appears to be appropriate for distant B-type stars. The final section of the paper by Feast and Thackeray is devoted to a discussion of the variation of the angular velocity $\omega(R)$ of the Galaxy as a function of the distance R from the galactic centre. The results are in general agreement with the curve derived from Schmidt's model of the Galaxy, itself based on 21-cm. radio observations. $\omega''(R)$ definitely appears to be positive rather than negative. A negative value, obtained in some earlier investigations, is very unlikely on general dynamical grounds.

Australian Biochemical Society

THE Australian Biochemical Society held its third annual general meeting in the Medical School, University of Adelaide, during August 18–20. At this meeting fifty-three papers were presented, and the second annual lecture of the Society was given by Mr. Hedley Marston, on "The Biochemical Function of Cobalt". The present membership is 280, and this year's president is Prof. R. K. Morton, of the Waite Institute, Adelaide. The honorary secretary is Dr. F. D. Collins, Department of Biochemistry, University of Melbourne.

Welsh Soils Discussion Group

UNDER the auspices of the Welsh Plant Breeding Station and the Departments of Agricultural Chemistry, Geography and Geology in the University College of Wales, Aberystwyth, a Soils Discussion Group has been formed, which held its first meeting on October 29. Some of the members of the Group are members of the British Society of Soil Science, which has recently lent its support to the formation of local groups to concentrate on soil studies in their local areas. Some thirty members attended the first meeting, including Dr. Alex Muir, director of the Soil Survey of England and Wales, and some members of the staff of the Departments of Agricultural Chemistry at the University College of North Wales, Bangor, of the Nature Conservancy (North Wales), of the Forestry Commission (Aberystwyth) and of the National Agricultural Advisory Service (Trawscoed). The first meeting was addressed by Dr. Nicholas Rast (Geology Department, Aberystwyth) on "Geochemistry in the Service of the Soil". The second meeting of the Group will be held in Aberystwyth at the Department of Geography on February 4, when Mr. James A. Taylor (Department of Geography) will lecture on "Slope, Climate and Soil". A third meeting will be held on April 22, when Dr. Rice Williams (Trawscoed) will introduce the subject "The Soils of the Aberystwyth Area". Further information can be obtained from J. A. Taylor, Department of Geography, University College of Wales, Aberystwyth.

U.S. National Research Council Conference on Fracture

THE National Academy of Sciences – National Research Council is organizing a seminar on "The Atomic Mechanisms of Fracture" to be held in Cambridge, Massachusetts, during April 12–14, 1959, to discuss the following topics: theoretical aspects of fracture; cleavage; crystalline and non-crystalline fracture; fatigue and ductile fracture; high-temperature fracture. The conference is being sponsored jointly by the National Science Foundation, Office of Naval Research, Air Force Office of Scientific Research, and the National Academy of Sciences – National Research Council. Further information may be obtained from Dr. B. L. Averbach, chairman, or Dr. D. K. Felbeck, secretary, Conference on Fracture, National Academy of Sciences – National Research Council, Washington, D.C.

Announcements

DR. M. L. M. SALGADO, soil chemist and acting director, has been appointed permanent director of the Coconut Research Institute of Ceylon.

THE following were recently elected to office in the Mineralogical Society: *President*, Prof. C. E. Tilley; *Vice-Presidents*, Prof. L. R. Wager and Dr. A. K. Wells; *Treasurer*, Prof. J. H. Taylor; *General Secretary*, Dr. G. F. Claringbull; *Foreign Secretary*, Dr. L. J. Spencer; *Editors of the Journal and Abstracts*, Dr. M. H. Hey and Dr. N. F. M. Henry.

THE Geological Society of London has announced the award of R. H. Worth Prizes as follows: to Mr. E. W. J. Moore, in recognition of his work on the goniatite succession of the Carboniferous rocks of the north of England and Ireland; and to Mr. C. W. Wright, in recognition of his researches on the stratigraphy and faunas of the English Cretaceous rocks, and especially on the Cretaceous Ammonoidea.

AN informal discussion on "Relaxation Processes" will be held under the auspices of the Faraday Society in the Department of Chemical Engineering of the Imperial College of Science and Technology on November 27. An introduction by Prof. A. R. Ubbelohde will be followed by contributions by Prof. C. J. F. Bottcher (Leyden) on dielectric relaxation; Dr. Vera Daniel (Electrical Research Association) on dielectric relaxation in crystals containing hydrogen bonds; Mr. W. Reddish (Imperial Chemical Industries, Ltd., Plastics Division) on relaxation in high polymers in the solid state; and Dr. J. Lamb (Imperial College) on ultrasonic relaxation in liquids. Further information can be obtained from Dr. J. C. McCoubrey, Department of Chemical Engineering, Imperial College of Science and Technology, London, S.W.7.

IN *Nature* of October 18, p. 1060, the list of Waverley awards was printed; a special award was announced in the official list as being made to Mr. M. D. Lilley. This was incorrect; the award was made to Miss M. D. Lilley, of Aplin and Barrett, Ltd.

ERRATUM. In the communication "Removal of Gases in High Vacuum Systems by Metal Abrasion", by M. E. Haine, E. W. R. Francis and R. N. Bloomer in *Nature* of October 4, p. 931, par. 2, line 7, for "litres/µsec." read "litre microns per sec."; the 'litre micron' is a unit of quantity of a gas where the volume of the gas is in 'litres', the pressure of the gas is in 'microns' (10^{-3} mm. mercury).

ORIGINS AND PHILOSOPHY OF TECHNOLOGY

LARGE corporations both in the United States and Britain have recently been giving attention to the more metaphysical aspects of the power they embody or produce, and considering the direction of the steps they intend to take in the second half of the twentieth century. In the United States, General Motors employed Peter Drucker to sketch for them "The Concept of the Corporation". In Britain, from the periphery of an industrial conference, similar heart-searchings are visible. Perhaps the best description for this activity is Adolf Berle's "Matrix Work", which he defined as "tending towards a body of sophisticated thinking whose aim, properly organized, is a concept of a community making for the good life".

Big bites into the edges of this vast and important sphere of thinking have just been made by the Electricity Council. Its chairman, Sir Henry Self, is particularly well qualified to do so, for in the midst of a distinguished career at the Board of Trade, the Post Office, the Foreign Office, the War Office, the Air Ministry and the British Electricity Authority, he has found time to supplement his originally scientific training by separate academic qualifications in mathematics, divinity, classics and philosophy. Having ploughed, harrowed and sown such diverse fields, all in their way fertile, he has now been winnowing the harvest of a life-time. Moreover, as president of the Modern Churchman's Union he is particularly concerned with presenting in contemporary terms a teleology of the modern world. He sees the universe as a complex of experience in every conceivable form at any possible level. He cites the collect in the "Book of Common Prayer" that prays for the grace not only to "read, mark and learn" but also to "inwardly digest" that which is "written for our learning". His introduction to the eight lectures* which were delivered to an invited audience of members of the senior staff of the Electricity Supply Industry in the autumn of 1956 emphasizes the inward nature of this digestive process.

As an aperitif, he has assembled three well-known figures to present the fruits of their work on the history of science: Prof. H. Dingle, Prof. D. McKie and Dr. P. Dunsheath. Each takes two strands of human thought and development which has fundamental significance for an understanding of our times and which, in Sir Henry Self's view, can be used as "the basis for future development of twentieth century life". Prof. Dingle presents us with Galileo and the beginnings of modern science, Prof. McKie follows on with the Royal Society and the scientific academies, and of course Lavoisier and the beginnings of modern chemistry. Prof. Dingle returns with a lecture on the nineteenth century and the expansion of the physical sciences, and Dr. Dunsheath with two lectures on the engineer and human progress. Sir Henry Self has not only given the introductory and the concluding lecture but has also published a further booklet*, treating in a complementary way twentieth century science and its implications for modern thinking. In this he confines himself to the exact sciences, but promises us further supplements on biology, medicine and psychology.

To the philosopher these two booklets are interesting and significant in that they reveal Sir Henry as a disciple of that great scientific statesman, Viscount Haldane, to whom, as much as any man, we owe the foundation of the Department of Scientific and Industrial Research. For he sees society evolving through community, creative adventure and the pursuit of truth. He is concerned with the bipolar nature of man. As a twentieth century mystic in the tradition of Boehme, William Law and Coleridge (though he does not shelter behind their names) he says "we have got to try and break from the bad habit which has grown over seven centuries whereby we are so proud of our empirical development, of the idea of trial and error, experiment and test, that having developed that we have thrown away the origins, the sources, out of which it sprang". These origins and sources show man, not as a super-computor capable of grinding out thoughts, words and ideas with a brain and a nervous system, but a living embodiment of ideas which have enduring eternal value.

Texts are out of fashion. If one were to be put on the front of these two booklets it would be *Romans*, i, 20: "For the invisible things of him from the creation of the world are clearly seen, being understood by the things that are made".

IONS OF THE TRANSITION ELEMENTS

A GENERAL discussion organized by the Faraday Society on "Ions of the Transition Elements" was held in Dublin during September 9-11. The main object was to consider the electronic structures and properties of these ions, particularly when included in complexes. A further object was to bring together physicists whose work was concerned with the structures of these ions and theoretical and experimental chemists whose interests lay in the same direction. It was most fortunate that both Prof. L. Pauling (California Institute of Technology) and Prof. J. H. Van Vleck (Harvard University) could be present, for their names are intimately connected with two of the most important theories that have been applied to the electronic structures of these compounds.

Two introductory papers at the beginning of the meeting were given by Dr. J. W. Linnett (University of Oxford) and Prof. M. H. L. Pryce (University of Bristol). The former surveyed the theories and experimental methods that have been employed, while the latter considered, in very general terms, the special features of the electronic structures of these ions from the physicist's point of view.

The first session was devoted to four papers which dealt with optical absorption. The first, by Dr. W. P. Doyle and G. Lonergan (University College, Dublin), described some measurements on the transmission of radiation by films of cobaltous and nickelous oxides between 360 and 1,000 mμ thick. The first maxima for both were interpreted as exciton transitions. The results were discussed on the basis of crystal field theory. The next two papers both dealt with the absorption spectra of transition metal ions in lattices of Al_2O_3. Prof. Pryce and W. A. Runciman (Harwell) studied trivalent vanadium in corundum, while Dr. S. Sugano and Dr. Y. Tanabe (University of Tokyo) considered trivalent chromium in ruby. The former workers succeeded in resolving the fine structure of two absorption bands and then considered theoretically the energy-levels for two *d*-electrons in a trigonal field. Sugano and Tanabe reported on the Cr^{3+} line spectrum in ruby and also discussed its interpretation. Prof. H. Hartmann and H. Müller (University of Frankfort) measured the spectra of the hexa- and heptahydrates of nickel sulphate to compare with calculations that had been made on the $Ni(H_2O)_6^{2+}$ ion. The results satisfy the theoretical requirements. A splitting of the main bands, indicating a departure from octahedral symmetry, was observed. The discussion at this session was mainly concerned with the reasons why certain substances were very intensely coloured.

The next five papers dealt with the application of paramagnetic resonance spectroscopy to transition metal ions. Dr. J. Owen (University of Oxford) reviewed the use of electron- and also nuclear-resonance to measure electron transfer. He also considered superexchange between pairs of iridium ions in mixed crystals of $(NH_4)_2(Ir,Pt)Cl_6$ containing sufficient iridium to ensure the presence of enough pairs of iridium ions which were nearest neighbours, but which had no other iridium neighbours. Dr. W. Hayes (Argonne National Laboratory) had studied ions such as Cr^+ and Fe^+ contained in a sodium fluoride lattice and produced there by γ-rays, X-rays or electrons. The fluorine hyperfine structure was used to measure the amount of electron transfer to the fluorines. Prof. J. E. Wertz, J. H. E. Griffiths and J. W. Orton (University of Oxford) and P. Auzins (University of Minnesota) described experiments with single crystals of magnesium oxide which contain iron group impurities. Because of the high dilution and exact cubic symmetry the lines are very narrow and in some specimens 200 lines were observed. These spectra can be used to study lattice defects.

J. F. Gibson, Dr. D. J. E. Ingram and Dr. D. Schonland (University of Southampton) presented results for electron resonance measurements of ferrihæmoglobin derivatives. A molecular-orbital treatment for these square-bond derivatives was given and the conclusions compared with the results for this and similar copper and cobalt complexes. Dr. J. S. Griffith (University of Cambridge) gave a theoretical treatment of the electronic structures of these complexes, his approach being a crystal field one. He examined his conclusions in relation to the electron resonance and magnetic susceptibility measurements.

The next two papers dealt with magnetic properties. Van Vleck discussed the magnetic anisotropy of crystals and the occurrence of inverted crystalline energy-levels. He concluded that, while the cubic part of the field is quite stable, the non-cubic part may be very dependent on the nature of the cation. Dr. B. N. Figgis, Dr. J. Lewis, Prof. R. S. Nyholm and R. D. Peacock (University College, London) measured the magnetic susceptibilities of some complexes of osmium, ruthenium, rhenium and iridium over a temperature range. The configurations de_t^3, de_t^4 and de_t^5 were involved. The results were discussed in terms of Kotani's theory.

Dr. C. K. Jorgensen (Technical University of Denmark, Copenhagen) discussed the decrease in repulsion between electrons in the *d*-shell of a complex ion compared with that in a free ion. The effect is due partly to an expansion of the *d*-orbitals because of increased screening and partly to their participation in covalent bonding. Prof. D. P. Craig and E. A. Magnusson (University College, London) also discussed this effect from a theoretical point of view and concluded that the effect could be largely explained without electron transfer into the 3*d* orbitals.

Dr. J. Chatt, L. A. Duncanson, B. L. Shaw (Imperial Chemical Industries, Welwyn) and L. M. Venanzi (University of Oxford) described measurements using infra-red spectra of the N—H vibration frequencies in various amine complexes. They discussed their results in terms of the extent and type of the electron drifts taking place. Dr. R. J. P. Williams (University of Oxford) showed that the stabilities of complexes cannot always be correlated with the ligand field-splitting factor. He concluded that stabilities should be related only to the ground-state properties and not to the excitation measured by the splitting factor.

Dr. L. E. Orgel (University of Cambridge) discussed the structure of a number of transition metal oxides, considering in particular distortions from a regular arrangement. He also examined the relation of this to the phenomenon of ferroelectricity. N. S. Hush (University of Bristol) presented graphs showing the variation in internuclear separation for the halides, oxides, etc., of the transition metals of the first long period. He also made calculations relating to these distances and contractions in them.

Dr. L. A. K. Staveley and T. Randall (University of Oxford) described measurements they had made of the heats of formation of a large number of complexes involving ethylenediamine tetraacetic acid. Combining their data with measurements of stability constants, they obtained entropy changes. The values were compared with one another and it was found that they fell into several sets. This was discussed. Dr. A. A. Vlcek (Academy of Sciences, Prague) described some work on polarographic half-wave potentials of a series of complexes and found that the potential could be correlated with the position of the ligands in the spectrochemical series. This and other results were then discussed in terms of the mechanism of the electrode process.

Throughout the meeting there was active discussion between the physicists and those chemists whose interests were definitely on the theoretical side or tended that way. But at times it did seem that there is still a great need for a better presentation of the theoretical ideas and nomenclature to the chemists whose activities are more largely experimental.

J. W. Linnett

THE CENTENARY OF 'DARWINISM'

THE Linnean Society has issued a special number of its journals in celebration of the centenary of the first publication of the theory of evolution by natural selection in the papers by Darwin and Wallace given to the Society in 1858*. The number contains thirteen papers, mostly by Fellows of the Society. Three of these deal with Darwin and the development of his theory during the intervening century, and the rest with modern work on evolution, five botanical and five zoological.

The first of the three contributions on Darwin's life and theory is Sir Julian Huxley's lecture on "The Emergence of Darwinism", which was given at the inaugural meeting of the fifteenth International Congress of Zoology last July. The lecture is an evaluation of Darwin's work in the light of our more recent knowledge. In particular, Huxley stresses the part of good fortune in Darwin's career, especially in providing him with the background required for his work. Even his delay in publishing his theory was fortunate, for the world was not ready for it earlier. So also was the intervention of Wallace, without which he might never have published, or, at least, not in the readable form in which it appeared. The lecture gave a most appropriate introduction to the Congress—as it also does to this publication—in emphasizing Darwin's outstanding quality as a biologist, not always sufficiently appreciated in modern times.

In his essay on Darwin's views on embryology and evolution, Sir Gavin de Beer discusses chiefly how far Darwin believed in Haeckel's theory of recapitulation. In the first edition of "The Origin" he was unwilling to accept the essential thesis of the theory, that life-histories evolve by addition of new stages at their ends, but he seems to have been persuaded by Fritz Müller and Haeckel to a still somewhat cautious acceptance, being in this matter led astray, perhaps because he realized that his knowledge of embryology was not wide. de Beer also believes that in at least one quotation Darwin anticipates the theory of pædomorphosis. This seems, to me, at least doubtful; the quotation can be read as doing no more than express doubts about the more extreme forms of the recapitulation theory.

In his article on "Darwin, Wallace and 'Preadaptation'", Dr. Harrison Matthews discusses the intellectual climate at the time of the publication of "The Origin", emphasizing, as did Sir Julian Huxley, the value to Darwin of the progress of thought in the preceding years and of the fact that in 1859—but not ten years earlier—younger men such as T. H. Huxley were available to support the new theory.

As a zoologist and not a botanist, I cannot discuss the botanical papers in detail. In his presidential address on fossil plants, Dr. Hamshaw Thomas gives an account of a great deal of recent work and shows that much evolution in plants has been by development of new structures rather than by modification of structures already present—the parts of the flower are not modified leaves. Dr. W. B. Turrill in his Hooker Lecture discusses the evolution of floras, with special reference to the Balkan peninsula; Dr. E. J. H. Corner has a paper on change of function in the organs of plants and the part it has played in evolution; Prof. I. Manton writes on chromosome numbers and the phylogeny of ferns; and Dr. Darnley Gibbs on the production of chemical substances in plants.

The longest of the zoological papers is Dr. S. M. Manton's summary of her work on locomotion in the arthropods. This will be useful to many who are not specialists in the subject and find her original papers longer than they can absorb. Prof. O. M. B. Bulman has an interesting paper on the evolution of colonial form in the graptolites, and Dr. E. B. Ford writes on the work of the Oxford zoologists on evolution in natural populations. In a paper on the problems of reptile classification, Mr. F. R. Parrington discusses much recent work and comes to the conclusion that there is no reason for thinking the reptiles diphyletic; all their groups are descended from primitive captorhinomorphs which were already reptiles. Finally, Dr. G. Pontecorvo writes on the versatility in evolution shown by the hereditary systems of organisms, both in typical holozygotic reproduction and in more primitive types.

Anyone interested in one or more of the many subjects dealt with in these papers will find something of value in this publication. It seems an excellent way to celebrate the centenary.

WATER FLUORIDATION AND DENTAL CARIES

THE Swedish Royal Medical Board has submitted a report to H.M. The King of Sweden concerning the use of fluorides in the prophylaxis of dental caries.

Swedish experts have been considering for a long time the prevention of dental caries by means of fluorides. In 1952 the Swedish Royal Medical Board appointed experts to study the question, and in 1955 the Board reported to the Swedish Government that the addition of fluorides to drinking water would be a valuable means of preventing the widespread dental caries; but the four members of the Scientific Council of the Board were doubtful about possible toxic effects of fluorides, even at the low concentrations present in drinking water, and the Board then preferred to await the outcome of further research. Meanwhile, it recommended the prohibition of fluoridation of public water supplies.

In 1957, however, a committee, consisting of Prof. Sven Sellman, Prof. Yngve Ericsson and Prof. Allan Strålfors, considered the prophylaxis of dental caries with emphasis on the use of fluorides for this purpose. This committee has presented, since 1958, more than one report. Members of the Scientific Council of the Royal Medical Board have also expressed their views.

There is general agreement that there are three principal methods of prophylaxis of dental caries, namely, administration of fluorides by vehicles other than water supplies, such as tablets, milk, common salt, flour and bone-meal, which the committee cannot recommend until further investigations have been made ; topical application of fluoride to the teeth, which should, the committee thinks, be investigated clinically under the control of the Royal Medical Board ; and fluoridation of the public water supplies.

With regard to this last method, the Board now reports that fluoridation of public water supplies does not involve any demonstrable hazards to health. It should, however, be carried out under strict control and care should be taken that, where it is instituted, the people are not exposed to fluorides derived from any other sources, such as foods or industrial gases. The Board reports that it has been found that a concentration of about 1 mgm. of fluoride per litre of water will reduce the incidence of dental caries by about 50 per cent in children and young persons who have consumed this water all their lives. In other children the caries will be reduced roughly in proportion to the period of consumption of the water. Fluoride also seems to protect the teeth of middle-aged people. A slight mottling of the enamel of the teeth appears in some children who have drunk water containing 1 mgm. of fluoride per litre during the period of tooth formation.

The technique of fluoridation of water is simple and has been thoroughly tested, but it is not applicable to those large groups of people in Sweden who have no access to a public water-supply. In Stockholm and Gothenburg the costs of fluoridation have been estimated at 0·3–0·4 Swedish crowns per person per year, or, when it is restricted to school children, 3–4 crowns per child per year. At present, expenditure on the public dental service for school children is about 75 crowns per child per year, and dental caries is so widespread that all available means of combating it must be used. In Sweden the city of Norrköping fluoridized one of its two public water supplies five years ago, and in Uppsala, Eskiltuna and Hälsingborg the public water supplies naturally contain more fluoride than is used for artificial fluoridation. The Board points out that in other countries in which fluoridation is used no evidence has been found that it harms health, and that both the American Medical Association and the World Health Organization have unreservedly recommended fluoridation as an effective and safe means of preventing dental caries.

The World Health Organization Expert Committee on Water Fluoridation, in its first report*, also concludes that drinking water containing about 1 p.p.m. fluoride has a marked preventive action on caries and does not impair health, and that controlled fluoridation of water is a practicable and effective public health measure.

HOST – PARASITE RELATIONSHIPS

The subject of host – parasite relationships covers such a wide field that the four papers on this subject, presented on September 3 in Section *M* (Agriculture) of the British Association meeting in Glasgow, not unexpectedly had comparatively little in common. Nevertheless, this diversity of interest helped to emphasize the fact that few living creatures escape the attention of some parasite or other, and that many specialized adaptations are necessary for parasitic life. Equally elaborate defence mechanisms have been evolved by potential hosts. The struggle for survival is governed very largely by the efficiency of these predatory or defending mechanisms.

Dr. J. A. Campbell (Moredun Institute, Edinburgh) explained that, among the insects, the true flies or Diptera apparently adopted the parasitic mode of life comparatively late in their evolutionary history. For this reason the flies show various degrees of adaptation to parasitism which can provide some information on the probable course of development of the habit. Morphological studies provide good evidence that the blood-sucking habit was evolved independently at different times in the various families. The behaviour patterns among the higher flies (Cyclorhapha) suggests that the course of evolution developed from generalized feeding on a wide variety of hosts to a more specialized association within a narrow range of hosts and even to complete dependence on a single species.

The stable fly (*Stomoxys calcitrans*), for example, feeds on a wide range of hosts, including man and most farm animals. Its larvæ can live in a variety of decomposing material, including dung heaps. The horn fly (*Lyperosia irritans*) is more specialized. The adults feed only on cattle, while the larvæ are confined to cattle dung. In the case of the sheep tick (*Melophagus ovinus*) dependence on a single host is complete. The fly has no wings, its larvæ are nourished *in utero*, and pupation occurs on the host.

There are many examples of the development of allergic sensitivity to insect bites. In some cases this can be recognized as a distinct clinical syndrome, such as Queensland itch in horses due to attacks of *Culicoides*. Insect saliva has been shown to be antigenic and the injection of this saliva can lead to the development of neutralizing antibodies in the host. So far as the hosts of blood-sucking flies are concerned, there is little doubt that for a variety of reasons some members of a species are more resistant to attack than others. There is no evidence, however, that specific immune reactions have any effect on the rate of infestation.

Dr. J. R. Norris (University of Glasgow) discussed the result of some recent work, largely done by two Canadian workers, Hannay and Angus, on the spore-bearing bacteria, *Bacillus thuringiensis*, which infect meal moth larvæ, and *Bacillus sotto*, which cause a septicæmic disease of silkworms.

Both organisms are capable of developing large protein crystals within their cytoplasm. If silkworm larvæ are fed with cultures of *B. sotto* containing both spores and protein crystals, they first become paralysed and then develop a septicæmia as the bacteria penetrate into the body cavity. If the same culture is injected into the body cavity, the organisms multiply and produce a septicæmia but no paralysis occurs. The spores themselves are harmless if fed without the protein crystals, although they cause a septicæmia without paralysis if injected into the body cavity. The protein crystals can be extracted from the bacteria and cause paralysis and death if fed to the larvæ, but not if injected into the body cavity.

It seems, therefore, that the protein crystals are necessary for the penetration of the bacteria through the gut wall, and that the protein itself requires to be activated by the gut contents before it becomes toxic.

Dr. Norris also discussed the possible relationships between *B. cereus*, *B. thuringiensis*, *B. sotto* and *B. anthracis*. It is quite clear that there are a number of interesting problems to be solved in connexion with the pathogenicity of this group of organisms.

Dr. W. Mulligan (University of Glasgow) described the results of recent work on parasitic bronchitis of cattle which has been done at the University Veterinary School. This disease, caused by the lung worm *Dictyocaulus viviparus*, is responsible for serious debility among calves both in Britain and abroad. Severe attacks can be fatal. The disease may sometimes be cured by drugs which destroy the worm in the bronchi, but the treatment is usually too late to prevent severe damage to the lungs. Nevertheless, cattle gradually develop a satisfactory immunity after repeated exposure to natural infections. Dr. Mulligan and his colleagues have shown that calves can be protected against experimental infections of lung worms by injections of immune sera from animals which have recovered from the disease. This [illegible]ation of the passive transfer of immunity [illegible]n beyond all reasonable doubt that calves [illegible]duce protective antibodies against *Dictyocaulus* [illegible]*arus*. The knowledge that circulating antibody [illegible] protect calves is of great value and a step forward [illegible] our understanding of the disease. Unfortunately, for practical reasons, this method of immunization cannot be used on the average farm. There is little doubt that the best method of prevention would be to find some means of artificially inducing an active immunity in otherwise susceptible animals. Attempts to immunize calves with various preparations of dead lung worms were apparently not very successful.

As natural infections gradually produce an active immunity, a trial was made with living vaccines consisting of larvæ which had been exposed to X-rays. It was hoped that larvæ treated in this way would survive for long enough in the calf to stimulate an active immunity and yet be incapable of causing progressive disease. Living vaccines of this type show great promise. It is thought that two doses of vaccine may give the best results, and an intensive trial is being made of this method. If these trials are successful, this vaccine should be of the greatest value to cattle owners in all parts of the world.

Dr. J. J. Bullen (Rowett Research Institute) discussed some of the factors which can influence the multiplication of pathogenic bacteria within a host. Examples were chosen from two experimental infections, enterotoxæmia of sheep and *Clostridium welchii* type *A* infections in embryonated hen's eggs.

The organism responsible for enterotoxæmia of sheep, *Cl. welchii* type *D*, is a normal inhabitant of the intestine. In certain circumstances, these bacteria multiply extremely rapidly and produce large quantities of toxin which is absorbed and kills the sheep. The disease cannot be reproduced in normal sheep fed on ordinary diets such as hay even if large numbers of *Cl. welchii* type *D* are introduced directly into the intestine. Viable counts of the bacteria in the living animal show that the bacteria cannot multiply fast enough to maintain their numbers and are soon removed by the normal flow of the intestinal contents. If the diet is suddenly changed, to wheat, for example, and the sheep overeats, the rumen becomes filled with undigested food. In the intestine this provides an ideal substrate for *Cl. welchii* type *D*. Very large numbers of the bacteria accumulate in the intestine. Large quantities of toxin are produced and the animal dies from acute enterotoxæmia. Thus, the diet of the sheep appears to play an important part in the development of this disease.

The experiments with eggs show that suitable antisera and, in certain circumstances, normal sera, can protect embryonated hen's eggs against normally fatal infections with *Cl. welchii* type *A*. The sera and bacteria are injected into the allantoic cavity. In unprotected eggs the organisms grow in the allantoic fluid and then invade the tissues of the embryo. In protected eggs the growth of the bacteria stops after an hour or two. There is no cellular response on the part of the host and no phagocytosis. Experiments of this kind appear to be useful for investigating the effect of sera on the growth of pathogenic organisms in the living host.

J. J. BULLEN

CHARGE-TRANSFER PROCESSES

A SYMPOSIUM on "Charge Transfer Processes", sponsored by the division of the Chemical Institute of Canada devoted to physical chemistry, was held during September 4–5 at the University of Toronto. The meeting, which had been organized under the chairmanship of Dr. B. E. Conway (University of Ottawa), was concerned with various aspects of the physical chemistry of reactions in which transfer of a formal charge occurs. Both homogeneous redox reactions and heterogeneous electrochemical reduction and oxidation processes were considered. About seventy-five physical chemists from the United States, Great Britain and Canada attended the academic sessions. Twenty-seven papers were presented, and each author was allowed ten minutes to describe the essential results of his work, all papers having been preprinted and circulated to participants several weeks before the meeting. About half the total time of the meeting was devoted to erudite and lively discussion of the papers presented. The meeting was honoured by the presence of a number of invited speakers from overseas, including Dr. D. J. G. Ives (Birkbeck College, London), Dr. J. E. B. Randles (University of Birmingham) and Dr. R. Parsons (University of Bristol). Prof. A. Frumkin (Academy of Sciences, Moscow), who had been invited, sent a paper for presentation but was regrettably unable to be present. On the evening of September 4, participants at the symposium repaired to St. Michael's College for a reception and later took dinner at the Howard Ferguson Hall.

Prof. F. E. W. Wetmore (University of Toronto) opened the meeting by welcoming the participants. The first session, on "Homogeneous Processes", with Dr. B. E. Conway in the chair, was opened with a paper by Dr. H. Taube (University of Chicago) on bridging and simple ligand effects in electron transfer reactions; Dr. Taube discussed changes which took place in the inner and outer co-ordination spheres of ions when these ions underwent oxidation or reduction. This was followed by theoretical contributions by Dr. K. J. Laidler (University of Ottawa) on electron-transfer reactions in aqueous solutions, and by Dr. R. A. Marcus on electrochemical and chemical-electron transfers. In these papers the factors involved in the electron transfer process and the solvent redistribution which occurs upon the transfer of a charge were examined. In the paper by Dr. K. J. Laidler, repulsion effects which arise upon the approach of ferrous and ferric ions in aqueous solution were calculated quantitatively, allowing for dielectric saturation. Electron transfer occurs by tunnelling. An optimum free-energy barrier exists for which the rate constant has a maximum value. A free energy of activation in good agreement with that determined by experiment was deduced. The applicability of the Franck–Condon principle to these processes was discussed at length. Dr. J. Halpern (University of British Columbia) examined the applicability of the principle of equi-valence change to inorganic oxidation-reduction reactions in terms of the kinetic parameters of a number of selected redox reactions. Drs. I. H. Henderson, R. L. Haines, E. G. Lovering and E. J. Casey (Defence Research Board, Canada) presented data on the equivalent redox potential of aqueous solutions under γ-irradiation. The session on homogeneous processes was concluded with two papers on the mechanism of anomalous proton mobility in hydrogen-bonded systems. Dr. M. Kilpatrick (Illinois Institute of Technology) discussed the limiting conductance of lyonium and lyate ions with particular reference to some anomalous non-aqueous systems, and Dr. B. E. Conway, speaking on the role of proton tunnelling in certain charge transfer processes, described measurements on the conductance of heavy-ice and discussed the theoretical significance of the ratio of mobilities of hydrogen ions and deuterium ions in water, heavy-water and the corresponding ices, in terms of a proton-tunnelling mechanism. A theoretical examination of the possibility that proton tunnelling also occurred in certain electrode processes involving hydrogen was given and criteria for recognition of such an effect were presented.

The second session, with Dr. J. E. B. Randles in the chair, was devoted to the mechanism of cathodic electrochemical reactions. The mechanism of electrolytic silver deposition was discussed in a paper by Drs. W. Mehl and J. O'M. Bockris, who had used a galvanostatic technique. The results, together with certain theoretical considerations, led to the conclusion that surface migration of adsorbed silver atoms or 'partial ions' was the rate-determining process at low cathodic potentials, while ionic transfer from the double-layer to the surface was the slow step at higher potentials. Dr. C. V. King (New York University) discussed the kind of information that can be obtained from studies of exchange between metals and their ions in solution, and emphasized that care must be taken in the interpretation of exchange data owing to complications arising from bulk diffusion and other factors. The mechanism of growth of electrolytic metal whiskers was discussed in a paper by Dr. D. A. Vermilyea (General Electric Co.) in terms of the theory of crystal growth and the role of adsorbed inhibitors. Some abnormal hydrogen electrode reactions at gold were described by Dr. D. J. G. Ives (University of London) and a desorption reaction involving H_2^+ molecule-ions was discussed in an attempt to rationalize observations concerning reduction of tungstic oxide 'at a distance' from the electrode. Mr. A. Antoniu and Dr. F. E. W. Wetmore (University of Toronto) gave some further data on the hydrogen evolution reaction at silver. Inflected Tafel lines exhibiting slopes of 0·059 and 0·112 were observed as found in previous work, and the heats of activation ($\Delta H^{\ddagger}$) were determined for the two parts of the lines. A difference of about five kilocalories in $\Delta H^{\ddagger}$ for the two processes involved was deduced; a change of mechanism of the reaction with increasing cathodic potential was indicated. Experiments on transport of hydrogen through palladium-clad electrodes were described in a paper by Drs. S. Schuldiner and J. P. Hoare (U.S. Naval Research Laboratory). Diffusion was detected by measurement of the polarization built up on the non-polarized side of a diaphragm electrode. The effect of cladding other metals (iron, nickel, gold) with palladium was examined.

The third session, on September 5, with Dr. B. E. Conway in the chair, was concerned with electrochemical reductions other than those involving hydrogen or metal deposition. Dr. J. E. B. Randles discussed the determination of kinetic parameters of redox reactions from current-potential curves and
a.c. impedance methods and referred to exp
results on the V^{3+}/V^{2+} reaction at mercury el
The two methods give similar results if appr
calculation of concentration polarization effec
made. The mechanism of reduction of chloraq
chromium-III ions in acid media, studied at the dro
ping mercury electrode, was discussed in a paper by Drs. H. Elving and B. Zemel (University of Michigan). At low acid concentrations a dual electron-transfer mechanism involving the electrode and chromium-II ions is suggested, while for $[CrCl_2.4H_2O]^+$ in 12 *M* hydrochloric acid a simple direct electron-transfer process is indicated. Dr. M. J. Allen (Ciba) described some problems in the study of organic electrochemical reductions.

A group of papers then followed on anodic processes. Dr. E. S. Snavely and N. Hackerman (University of Texas) described some analytical and coulombic studies on the anodic passivation of iron, and Dr. M. Cohen (National Research Council of Canada) discussed the formation and properties of passive films formed on iron under various conditions, for example, the presence or absence of oxygen or the presence of inhibiting ions. Some theoretical considerations on the mechanism of growth of anodic oxide films were presented by Dr. L. Young (British Columbia Research Council). Dr. B. E. Conway and P. L. Bourgault (University of Ottawa) described some studies on the kinetics of self-discharge of nickel – nickel oxide electrodes. The decay of electromotive force and rates of evolution of oxygen had been measured on open circuit over a wide range of concentrations of potassium hydroxide and the kinetics interpreted in terms of a scheme of consecutive reactions for rate-determining oxygen evolution at anodic sites on the oxide.

The final session of the meeting, with Dr. S. Schuldiner in the chair, was concerned with the double-layer and adsorption at electrodes. The correlation between double-layer capacity and kinetics of electrode processes was examined in a paper by Drs. M. Breiter and P. Delahay (Louisiana State University), and Drs. R. S. Hansen and D. A. Hickson (Iowa State College) presented some interesting results on the apparent dependence on frequency of the capacity of the double-layer; relaxation times for water in the double-layer as high as 10^{-2} sec. were deduced. This occasioned some discussion, since it was pointed out that even in the ice lattice, where the water is strongly bound, the relaxation time is much smaller (about 10^{-6} sec.). Dr. R. Parsons (University of Bristol) read the paper by Prof. A. Frumkin (Academy of Sciences, Moscow) on the influence of surface-active anions on the electro-reduction of persulphate anions at negative potentials; the acceleration of the reduction of $S_2O_8^{2-}$ which was observed in the presence of surface-active anions was explained in terms of their effect on the potential (ψ_1) at the outer Helmholtz plane in the double-layer. Specific effects of cations on the kinetics required that a local fluctuating ψ_1-potential due to interaction of the adsorbed anions with cations in the double-layer be considered. A general thermodynamic analysis for the determination of heats of adsorption in ionic systems by electrocapillary studies was given in a paper by Dr. R. Parsons and results obtained for the isotensile heats of adsorption of potassium iodide at mercury were discussed. The meeting concluded with two papers describing the adsorption of hydrochloric acid and aromatic aminium salts at mercury by the electrocapillary method (Drs. E. Blomgren and J. O'M. Bockris, University of Pennsylvania) and the adsorption of methylene blue at mercury by collecting a large number of mercury drops which had fallen through the solution and analysing for the dye carried down in the double-layers of the drops (Drs. J. M. Los and C. K. Tompkins, University of New Brunswick). Some results from studies on the direct determination of adsorption of organic ions at solid metals were presented by Dr. B. E. Conway and Mr. R. G. Barradas in discussion.

Most of the papers presented at the meeting will be published early in 1959 in the *Canadian Journal of Chemistry*.

B. E. CONWAY

EAST MALLING RESEARCH STATION

ANNUAL REPORT

THE annual report of East Malling Research Station for 1957* contains some important research findings. A new semi-dwarfing apple rootstock, *M* 26, is described by W. S. Rogers; it is intermediate in vigour between *M* IX and *M* VII, and so fills a unique place. The elimination of virus from strawberry clones by heat therapy increased the fruit yield of several varieties, though the crop ripened later, and was more prone to *Botrytis* rot than untreated plants. In Early Cambridge and Rearguard, however, there was excessive vigour and a decrease in yield (W. S. Rogers and Muriel G. Fromow). Rooting and growth of root cuttings from the apple rootstock Crab *C* declined with increasing age of establishment of the parent plant, according to results obtained by R. J. Garner and E. S. J. Hatcher. Raspberry breeding work, by R. L. Knight and Elizabeth Keep, is now mainly concerned with the introduction of resistance to the virus vector *Amphorophora rubi* and to cane spot and *Botrytis*, while interspecific hybrids are being sought between black-currant and gooseberry. The apple breeding work of H. M. Tydeman shows progress towards a late-flowering variety which will be resistant to scab and mildew.

Two papers in the physiological section show that, in the British climate, temperature is perhaps the most important factor in fruit growth. C. R. Hancock and H. W. B. Barlow show that growth-rate of Crab *C* shoots was related to temperature and day-length, though the final internode length was less dependent on temperature and had little relation with the daily period of light. The same authors found that the effects on leaf growth of a summer gale in 1956 were mainly due to the fall in temperature. D. H. Maggs has compared growth of the rootstocks *M* II and *M* XVI with differences in time of leaf-break eliminated; the former produced more stem and the latter more root for plants of the same weight. *M* II had a smaller increase in weight produced per gram of leaf than *M* XVI.

Symptoms of magnesium deficiency in apple rootstocks can best be eliminated by foliar spraying with Epsom salts. Elsie M. Ford shows that this method is better than soil application and that it is not enough merely to remove the symptoms, for three sprays are necessary to bring increased vigour.

The virus disease known as little cherry causes serious damage in North America, and now A. F. Posnette and R. Cropley have reported it in Great Britain. G. W. F. Sewell and J. F. Wilson report another new trouble in that some common hop garden weeds have been found susceptible to the 'progressive' strain of the hop wilt fungus *Verticillium albo-atrum*. There were earlier indications that the hop virus 'nettlehead' was in some way linked with nickel content of the plant. J. T. Legg and P. J. Ormerod find that the symptoms of nickel toxicity and of nettlehead are distinct, though presence of the virus is associated with higher contents of some heavy metals than are found in healthy plants. R. S. Pitcher shows that the life cycle of the currant leaf midge *Dasyneura tetensi* varies considerably from year to year. This brings difficulties of timing control measures and demonstrates the necessity for more persistent toxicants. A study of *Blepharidopterus angulatus* by R. C. Muir is mainly an evaluation of the capture–recapture method of estimating orchard insect populations. Phytotoxicity studies by A. H. M. Kirby and Margery Bennett show that a number of acaricides are safe to use on the varieties of black currant and plum used for test. On the other hand, phenyl mercury chloride caused direct damage to pears in each season, irrespective of weather conditions.

* Kent Incorporated Society for Promoting Experiments in Horticulture. Annual Report of East Malling Research Station, 1st October, 1956, to 30th September, 1957. (Forty-fifth year.) Pp. xxv+173. (East Malling, Maidstone: East Malling Research Station, 1958.) 17*s.* 6*d.*; 2.50 dollars.

The report contains the text of the Amos Memorial Lecture by F. C. Bawden on viruses and virus diseases —a most useful general review. It has also papers on methods of recording, sampling and experiment. There is a detailed paper on soil management effects on a number of chemical and physical properties of the soil (J. E. Goode and G. C. White) the practical implications of which are discussed in one of the four bulletins for fruitgrowers. A review, however, should lay a train of anticipation leading to the detail of the report itself. It is a current guide to the enlarging horizon of the application of science to the culture of fruit.

NEW HYDROXYAMINO-ACIDS IN PLANTS AND THEIR IDENTIFICATION

Hydroxyvaline in *Kalanchoe daigremontiana*

THE first application of two-directional paper chromatography to the investigation of soluble nitrogen compounds in plants was reported in *Nature* in 1947[1], and paved the way for the recognition of many new free amino-compounds in plants. By the application of the new techniques, the list of naturally occurring amino-acids became rapidly extended, for hitherto the emphasis had been upon the demonstration, in the free state, of the protein amino-acids and of the amides, asparagine and glutamine. The course of these discoveries has been summarized in a series of reviews[2] which show the unexpected range of structure which natural amino- and imino-acids display.

The hydroxyamino-acids represent a special category of compounds which have been largely revealed by chromatographic methods, and, as will be seen, the final identification of these substances presents special difficulties and problems.

Prior to the development of paper chromatography, serine and threonine were the only non-phenolic hydroxyamino-acids known with certainty to occur widely distributed and free in Nature. Hydroxyproline and a hydroxylysine of uncertain structure were known in collagen but not known free in plants. Reports of the presence of β-hydroxyvaline[3] and β-hydroxyglutamic acid[4] remained unconfirmed and eventually proved to be erroneous[5]. Since the application of chromatographic methods, the following hydroxyamino-acids have been found in plants: allohydroxy-L-proline[6]; hydroxy, methylproline[7]; 5-hydroxypipecolic acid[8]; 4 (or 3)-hydroxypipecolic acid[9]; homoserine[10]; γ-hydroxyglutamic acid[11]; dihydroxyglutamic acid[12]; γ-hydroxy, γ-methylglutamic acid[8c]; α-amino, γ-hydroxypimelic acid[13]; and α,ε-diamino, β-hydroxypimelic acid (tabtoxinine)[14]. However, only in the case of allohydroxy-L-proline[6] has the evidence for these new amino-acids been brought to completion by the synthesis of the compound in question followed by the resolution of the appropriate stereoisomer and the critical comparison, by appropriate physical and chemical methods, of the natural and synthetic products. In one difficult case, involving three centres of asymmetry, the amino-acid in question (tabtoxinine) on synthesis[15] was found to have a structure different from that first assigned (Braun, A., private communication). The final identification of new compounds with one or more centres of asymmetry, therefore, should include their stereoisomeric configuration; and this being so, more readily applicable methods of optical resolution are needed so that the final identification of these new substances need not lag so far behind their recognition as at present.

Information in both parts of this contribution will extend the general recognition of compounds of this type to include γ-hydroxyvaline and O-acetylhomoserine.

Hydroxyvaline was first recognized as an unidentified, ninhydrin-reactive spot on paper chromatograms of an alcohol-soluble extract of crowngall tumours from *Kalanchoe daigremontiana*[16] and was described as 'Unknown No. 75' in a review[2b]. Subsequent studies showed it to be present in leaves and stems also, but, as yet, only in this single species of *Kalanchoe*. The substance is not found in *K. beharensis, longiflora, sexangularis, marmorata, tomentosa, verticillata, gastonis-bonieri* or *pinnata*, nor has it been detected in the many other species of plants which have been examined in this laboratory chromatographically.

On hydrolysis of crude extracts, unknown 75 partially disappears with the concurrent appearance of a second unknown, No. 78, and glutamic acid. The position of Nos. 75 and 78 on a chromatogram are shown in Fig. 1. This preliminary result was first interpreted to mean that two unknown amino-acids occupied identical positions on the chromatograms, and that only unknown No. 75 broke down to give No. 78, while the acid-stable material in the same position as No. 75 was assigned the number 76.

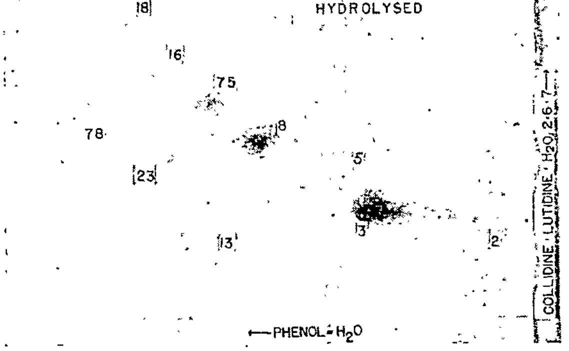

Fig. 1. Two-directional chromatogram, treated with ninhydrin, of the soluble compounds of *Kalanchoe daigremontiana* (copied from an original photograph in colour).
Numbered key to amino-acids: 2, aspartic acid; 3, glutamic acid; 5, glycine; 8, alanine; 13, arginine: 16, valine; 18, leucines; 23, γ-aminobutyric acid; 75 and 78, γ-hydroxyvaline and its lactone, respectively. (Nos. 75 and 78 react violet with ninhydrin)

Because of a general interest in glutamyl compounds[17], an attempt was made to isolate No. 75 and to determine its relationship to Nos. 76, 78 and to glutamic acid. An alcoholic extract from 60 gm. of lyophilized crowngall tumours of *Kalanchoe daigremontiana* was fractionated on 'Dowex'-50 × 4 after the methods of Partridge and Brimley[18]. Unknown No. 75 came off the column with the neutral amino-acids, whereas Nos. 76 and 78 came off the column with the bases, in fact, even slightly after arginine. In the ammoniacal eluate, No. 78 rapidly disappeared with the appearance of more of No. 76. Since several fractions then contained pure 76, it was easily shown that No. 76 was largely converted to No. 78 on acid hydrolysis and that ammonia hydrolysis reconverted No. 78 completely to No. 76. This tentatively identified No. 78 as a lactone with basic properties, produced by acid hydrolysis from the neutral hydroxyamino-acid, No. 76. Furthermore, unknowns Nos. 75 and 76 were not distinct but identical, and any confusion between them arose from the position of the equilibrium attained during acid hydrolysis, an equilibrium largely in favour of the lactone (No. 78) but with enough of the free amino-acid remaining to give the erroneous impression on chromatograms that a mixture of a stable and an unstable compound was involved. The appearance of glutamic acid on hydrolysis of the crude extracts is thus shown to be independent of the destruction of No. 75, and must arise from some other, still unidentified, source.

Having isolated No. 75 in the general manner indicated, an elemental analysis corresponded to the formula $C_{4\cdot97}H_{11\cdot33}NO_{3\cdot03}$ or $C_5H_{11}NO_3$; this could then be a hydroxyvaline. The Crumpler and Dent[19] test indicated an α-position for the amino-group and the ease of formation of lactone requires a γ- or δ-position for the hydroxy-group. Of the various compounds which would fit these requirements, α-amino, γ-hydroxy-*n*-valeric acid and α-amino-δ-hydroxy-*n*-valeric acid were obtained and shown to be readily separable from No. 75 on paper chromatograms, as was β-hydroxyvaline. The other two possibilities, namely, α-methylhomoserine and N-methylhomoserine, have not been obtained; however, neither α-methylamino-acids nor N-methyl amino-acids react quickly to give the typical violet colour with ninhydrin as does No. 75, and on this basis these two possibilities may also be tentatively eliminated.

At this point, all the indications were that No. 75 was γ-hydroxyvaline of unspecified stereochemical configuration, but this compound had never been synthesized and was unavailable for comparison. A new synthesis was required. One of us (E. S.) then prepared γ-hydroxyvaline by amination of α-chloro, β-methyl, γ-butyrolactone as follows.

The α-chloro, β-methyl, γ-butyrolactone was prepared by a modification of the method of Fleck and Shinz[20], hydrogenating α-keto, β-methyl, γ-butyrolactone in absolute ethanol with palladium-on-charcoal catalyst. The resulting α-hydroxy compound was converted to the α-chloro compound by refluxing with thionyl chloride in pyridine. This in turn was aminated in concentrated aqueous ammonia containing ammonium carbonate at 60° C. in a pressure flask for four days. This reaction mixture was passed over 'Dowex'-50 × 4, on which the amino-acid was retained and from which it was eluted with *N* ammonia. The product crystallized from the concentrated, syrupy eluate on addition of absolute ethanol, and after three recrystallizations showed a melting point of 209–11° C. (corrected). Elemental analysis gave C, 45·50; H, 8·25; N, 9·64; calculated: C, 45·11; H, 8·32; N, 10·5. Only the nitrogen value differed significantly from the calculated value.

Since the synthetic product and its lactone corresponded exactly with Nos. 75 and 78, respectively, on paper chromatograms in phenol – water, in butanol – acetic acid – water, and in collidine – lutidine – water, and because of the chemical evidence available, these two unknowns are now recognized as γ-hydroxyvaline and its lactone. Attempts to confirm this by reduction of natural γ-hydroxyvaline to valine with red phosphorus and hydriodic acid failed, only the lactone being formed in the treatment. Comparison of the infra-red absorption curves and the melting points of the synthetic and natural preparations showed differences, as would be expected since such comparisons are being made between a racemate which may contain both diastereoisomers and an optically active substance which is presumably a single stereoisomer.

The recognition of No. 75 as γ-hydroxyvaline now makes its isolation relatively easy. An extract of 128 gm. of lyophilized crowngall tumours from *K. daigremontiana* was evaporated to remove ethanol and was partitioned between water and chloroform to remove pigments. The aqueous layer was made acid (1 *N*) with hydrochloric acid and hydrolysed in the autoclave for an hour to form the lactone. The hydrolysate was filtered, evaporated to remove excess hydrochloric acid and then passed through an excess of 'Dowex'-50 in the ammonium form. Since the resin in this state retains only bases, the basic lactone, along with arginine and lysine, is retained. The column is eluted with 2 *N* ammonia and washed with water, then the eluate, boiled to hydrolyse the lactone and remove ammonia, is passed again through the same column. Again the bases are retained, but the γ-hydroxyvaline, now present as the neutral amino-acid, passes through and may be collected free of contaminating amino-acids. Following this procedure, 186 mgm. of crude product (melting at 215° C.) yielded 146 mgm. of recrystallized product (melting point 228° C.). A second crystalline form, decomposing at 248° C., may also be obtained under certain conditions. The pure product showed a specific optical rotation of (+) 10 deg. ± 0·5 deg. in water at 20° C.

Unknown No. 75 is therefore recognized as (+) γ-hydroxyvaline, but final and complete determination of structure awaits comparison with the optically active synthetic stereoisomers; in this respect, γ-hydroxyvaline presents the same problem as other new hydroxyamino-acids mentioned above.

O-acetylhomoserine in *Pisum*

HOMOSERINE is now known to occur somewhat abundantly in the vegetative parts of pea plants[1,2], in which it is supposed to arise from aspartic acid[3], though it is said to be absent from the seed[2].

During the chromatographic examination of alcoholic extracts of the various organs of the plant, namely, leaf, stem, root and fruit, the presence of a substance reactive to ninhydrin but unstable in acid was noted. This substance proved to be present most abundantly in the pea pod, that is, the pericarp, of this leguminous fruit. It disappeared when the extracts were subjected to mild acid or alkaline hydrolysis. The then unidentified substance was referred to by Grobbelaar[4] as unidentified substance No. 200, and by Steward, Zacharius and Pollard[5] in their summary of the new nitrogenous constituents of plants as No. 84.

The relative positions of this substance, and of homoserine, known to occur in *Pisum*, on chromatograms, are shown in Fig. 1. When the lactone of homoserine is also present, as when homoserine is treated with acid, it appears as a diffuse 'streak' moving faster than homoserine in the phenol direction. The instability in acid of the unidentified substance, and the fact that it yielded, on hydrolysis, only one ninhydrin-reactive substance (homoserine), led to the first recognition of this substance as a derivative of homoserine, other than the lactone.

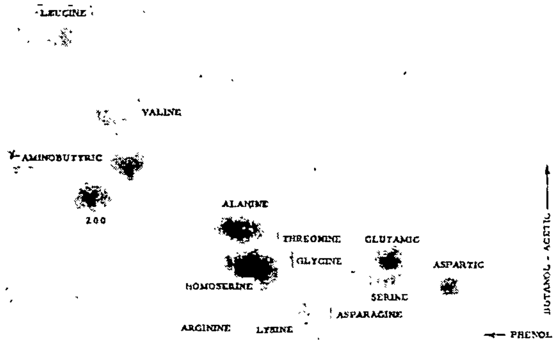

Fig. 1. Two-directional chromatogram, treated with ninhydrin, of the alcohol-soluble nitrogen compounds of *Pisum sativum* (copied from original photograph in colour)
No. 200 is O-acetylhomoserine, reacts violet. Under the conditions used, serine and glycine, asparagine and lysine were distinguishable by their colour reactions. Certain weak unlabelled spots are not positively identified

While a small amount of the substance in question was obtained from alcoholic extracts of pea shoots by paper chromatographic methods of Mueller[6], 35 mgm. of crystalline material were obtained from an extract made of the pea pods, from 4·5 kgm. of commercial peas. After clarifying the extract with basic lead acetate, lead was removed by hydrogen sulphide and the extract was evaporated at room temperature. The crystalline product was separated from the other constituents of the extract by the general method of Hirs, Moore and Stein[7]. Other attempted procedures of fractionation and isolation (absorption of the amino-acids on basic or acidic resins with the subsequent use of the appropriate eluting agent) failed, either because they were ineffective in separation or because this labile substance was decomposed. The procedure finally adopted was as follows.

The clarified pea extract was fractionated on a 15-cm. 'Dowex'-50 column, and the unknown substance emerged along with the neutral and acidic amino-acids. The acidic amino-acids were removed from the mixture, using an '*IR-4B*' column. Further successive treatments of the mixture on 'Dowex'-50 columns led to a final product contaminated only with some threonine, serine and proline. The final purification was accomplished on a cellulose-powder column (7 cm. × 65 cm.) by chromatography with *N*-butanol, acetic acid and water (9 : 1 : 2·9 by volume). The desired substance emerged from the column only slightly contaminated with proline. All the fractions which contained the substance desired were concentrated under reduced pressure at room temperature, yielding a small residue of yellowish substance. On solution in water, a waxy, insoluble, ninhydrin-negative material was discarded. The yellow aqueous solution was treated with activated charcoal, filtered through 'Celite', and the nearly colourless filtrate was concentrated *in vacuo*. By addition, drop by drop, of absolute ethanol, crystallization started and continued at low temperatures, and finally, by the addition of an excess of ether, 35 mgm. of crystals were obtained, washed with ether and dried over calcium chloride.

Despite the slight contamination with proline, evident even in the crystalline material, the elementary analysis corresponded to an acetylhomoserine (found C, 45·01 ; H, 6·80 ; N, 8·90 ; calculated for $C_6H_{11}NO_4$, C, 44·71 ; H, 6·88 ; N, 8·69 per cent).

Since the analysis does not distinguish between the N-acetyl derivative and the O-acetyl derivative of homoserine, both these substances were prepared from DL-homoserine. The methods adopted for these syntheses were as follows.

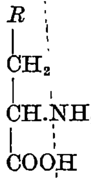
O-acetylhomoserine was unequivocally synthesized from an authentic sample of DL-homoserine by the method of Sakami and Toennies[8], as, in fact, Matsuo, Rothstein and Greenberg[9] have also reported.

For the preparation of the N-acetylhomoserine, the method of du Vigneaud *et al.*[10] was employed. Neither the N-acetylhomoserine so synthesized nor any other N-acetyl amino-acids tried (glycine, alanine, methionine and valine) reacted with ninhydrin on paper. This eliminated any possibility that the natural product was the N-acetyl compound.

In addition to the elementary analysis, the identification of the amino-acid in pea plants as O-acetylhomoserine then follows from the following chromatographic evidence in phenol and butanol–acetic solvents: (1) the product as isolated was identical with that present in the crude extract of peas; (2) the isolated and synthetic products behave identically on chromatograms and toward ninhydrin; (3) the hydrolytic products in acid and alkali obtained from the synthetic and isolated substances also behave identically on chromatograms and toward ninhydrin, and these are recognizable as homoserine and, in acid solution, its lactone which, in turn, were also tested chromatographically in other solvents (collidine–lutidine; pyridine–toluene).

As in the other cases referred to in the preceding communication, there still remains the problem of the final stereoisomeric configuration of the natural substance. Until the synthetic product is resolved, or is prepared from homoserine of known stereoisomeric configuration, the use of physical methods of comparison (infra-red analysis, etc.) is not conclusive. In fact, the configuration of natural homoserine in plants still remains to be established, since this evidence was not furnished in the paper by Miettinen *et al.*[1]. Although this final step remains to be carried out, the evidence here reported nevertheless establishes the occurrence of an O-acetylhomoserine as a new, free, natural substance in pea plants.

To conclude, it is interesting to note the structural relations between acetylhomoserine and certain other natural compounds which can be treated as substituted C4 amino-acids. All these contain the structure



$$\begin{array}{l} R \\ | \\ CH_2 \\ | \\ CH.NH_2 \\ | \\ COOH \end{array}$$

where *R* has the structure indicated in the compounds named below:

(*a*) if *R* is CH_3 the compound is γ-aminobutyric acid;
(*b*) if *R* is $CH_2.OH$ the compound is homoserine;
(*c*) if *R* is CHO the compound is aspartic-β-semialdehyde;
(*d*) if *R* is COOH the compound is aspartic acid;
(*e*) if *R* is $CH_2.NH_2$ the compound is α,γ-diaminobutyric acid;
(*f*) if *R* is CH_2OAc. the compound is O-acetylhomoserine;
(*g*) if *R* is $CH_2O.NH.CNH.NH_2$ the compound is canavanine;
(*h*) if *R* is CH_2ONH_2 the compound is canaline.

A similar series of compounds can be visualized in the next higher homologues; of these, however, only the members corresponding to the following possibilities are well known, namely: (*c*) = glutamic semi-aldehyde; (*d*) = glutamic acid; (*e*) = ornithine; and for these three the metabolic inter-relationships are well worked out, with proline being the related cyclic compound. In the C4 series, azetidine-2-carboxylic acid now appears as the cyclic compound which bears a similar relationship to the appropriate members of the C4 series[11].

It is interesting also to note that the substance γ-hydroxyvaline of the preceding communication differs from homoserine only by a methyl substitution or the β-carbon.

AUXINS AND THEIR EFFECT ON THE GROWTH OF UNICELLULAR ALGAE

Effect of Ethanol and Auxins on the Growth of Unicellular Algae

THE effect of auxins on unicellular algae has been the subject of numerous papers, but many of the reported findings contradict each other as to whether and how the auxins affect these organisms[1–3]. We re-examined this problem because algae, if they responded to auxin, would be ideal organisms for the study of the biochemical basis of this stimulation. Some of the earlier observations may be explained by the present communication, in which we report a stimulation of growth by ethanol in several unicellular algae.

Chlorella vulgaris (*A.T.C.C.* 11468) was cultured at *p*H 6 in medium I of Hutner *et al.*[4] with a ten-fold increase in sodium dihydrogen phosphate and the addition of 1·2 gm. per litre potassium nitrate. Growth assays were conducted essentially as described by Hutner *et al.*[5]. Growth was estimated by measuring the optical density of the cultures at 440 mμ in a Klett–Summerson colorimeter, since preliminary experiments had shown a linear relation between optical density and cell counts carried out with a hæmocytometer. Carbon analyses were carried out by oxidation in potassium dichromate–sulphuric acid and measurement of the absorption at 440 mμ. A

Table 1. The Effect of Addition of Ethanol on the Growth of *C. vulgaris*

Parts of alcohol added, v/v	Optical density, 440 mμ	Sum	Range
None	110, 111, 104	325	7
1 : 5 × 10⁶	127, 112, 107	346	20
1 : 10⁵	121, 120, 113	354	8
1 : 5 × 10⁴	137, 122, 142	401	20
1 : 10⁴	186, 183, 166	535	20
1 : 5 × 10³	104, 100, 135	339	31
1 : 10³	10, 12, 12	34	2
Sum of ranges			108

Factor for 5 per cent risk = 0·70 ; 108 × 0·70 = 74

Table 2. The Effect of Addition of 1 : 10,000 parts Alcohol (v/v) on the Carbon Content of *C. vulgaris* Cells

The amount of alcohol added equals 0·4 mgm. carbon per flask

	mgm. carbon found in cells per flask	Sum	Range	Average
No addition	0·27, 0·40, 0·34, 0·34	1·35	0·13	0·34
1 : 10,000 alcohol	0·62, 0·48, 0·66, 0·57	2·33	0·14	0·58
Sum of ranges			0·27	

Factor for 5 per cent risk = 1·63 ; 1·63 × 0·27 = 0·44.

dichromate solution which had been completely reduced with sodium sulphite served as a blank. The difference in absorption of the sample from that of unreduced dichromate solution is a linear function of the carbon content. Statistical analysis was carried out by Link and Wallace's method of allowances.

Table 1 shows the effect of very small ethanol concentrations on the growth of *C. vulgaris*. An approximately two-fold stimulation of growth is observed. Since this stimulation occurred at extremely low ethanol concentrations, it was of interest to establish whether the stimulation was due to the utilization of the ethanol as a carbon source by the cells. Table 2 describes the results of an experiment in which the carbon content of the cells from media containing ethanol is compared with that of cells grown with no added carbon sources. It can be seen that the gain in carbon content can be accounted for from the amount of carbon added in the ethanol. The fact that such small concentrations of ethanol have such a marked growth-stimulatory effect can be explained if it is realized that carbon dioxide is the growth limiting factor under the assay conditions in most of the earlier experiments. When this limitation is removed, as, for example, by placing the cultures on a shaking apparatus, the stimulatory action of ethanol is lost. As could be expected, low concentrations of ethanol also stimulated the respiration of *Chlorella* when measured in a Warburg apparatus in the dark.

Recently, several reports have appeared[6,7] which describe beneficial effects of low concentrations of ethanol in higher plant systems which were being used for auxin studies. In our system no stimulatory effect could be found in the presence or absence of added ethanol, using a number of different auxins and anti auxins at concentrations from 10^{-7} to 10^{-4} *M*. Similar results were observed in experiments using *Euglena gracilis* strain *z*, *Coccomyxa simplex* (*A.T.C.C.* 11471), *Chlorella pyrenoidosa* (*A.T.C.C.* 11469), *C. ellipsoidea* (*A.T.C.C.* 11466) and *Scenedesmus obliquus* (*A.T.C.C.* 11457).

Many of the earlier papers on the effect of auxins on algae did not specify how the auxin solutions were prepared, and the possibility that ethanol was used cannot be excluded. Brannon and Bartsch[8] used alcoholic solutions upon the advice of Dr. Zimmermann, one of the early authorities in the growth-substance field, and their results very closely resemble those presented in Table 1.

Further work now in progress will attempt to define experimental conditions under which the stimulation of algal cell division would be sufficiently large to afford the use of this system for biochemical studies.

We wish to acknowledge the able technical assistance of Miss Barbara A. Edwards.

Ethanol as a Carbon Source for the Growth of *Chlorella vulgaris*

During studies of the effect of β-indolylacetic acid on the growth of *Chlorella vulgaris*, Brannon No. 1, cultured in darkness at 25° C., evidence has been obtained that ethanol is active as a substrate for the heterotrophic growth of this organism. β-Indolylacetic acid was incorporated in certain experiments by the use of a stock solution, prepared as described by previous workers[1,2] and containing 100 mgm. β-indolylacetic acid and 2 ml. 95 per cent ethanol per litre. Glucose was used as carbon source and the inorganic salts were supplied as a Craig and Trelease[3] solution modified by using ferric ethylenediamine tetraacetate as the iron source, by addition of molybdic acid (0·017 mgm./l.), and by adjustment of the *p*H to 5·0. The activity of ethanol was detected when the alga was supplied with sub-optimal levels of glucose (for example, 0·02 per cent) (Table 1). The greater final yield, both in cell numbers (hæmocytometer count) and in algal dry weight (dried at 80° C. for 24 hr.) resulting from addition of ethanolic β-indolylacetic acid was not reproduced by equivalent concentrations of aqueous β-indolylacetic acid and occurred under conditions where the glucose was completely depleted from the medium by the alga (glucose estimated colorimetrically using a modification of Wager's method[4]) (Table 2). Increases of 0·117 (Table 2) and of 0·199 mgm./ml. algal dry

Initial population 100 cells/mm.^{3}

Carbon source	Cells/mm.^{3} after 240 hr.
1·0 per cent glucose	31,050
1·0 per cent ethanol	1,550
0·5 ,, ,,	1,450
0·1 ,, ,,	24,450
0·05 ,, ,,	19,000
0·01 ,, ,,	13,250

weight resulted in separate experiments from the addition of 20 mgm./l. β-indolylacetic acid as a solution containing about 0·316 mgm. ethanol/ml. ≡ 0·165 mgm. ethanol-carbon/ml.).

This enhancement of growth by ethanol was only observed when the culture medium contained limiting concentrations of glucose; with 0·02 per cent glucose the growth-curves (cells/mm.^{3}) in presence and in absence of ethanol were superimposed for the first 90 hr. of culture, but beyond this time the cultures receiving ethanol continued active growth while the control cultures entered the stationary phase. The optimum concentration of ethanol when used as sole carbon source was at or below 0·1 per cent (about 0·02 *M*) (Table 3); at 0·5 per cent, ethanol inhibited cell division as compared with the carbon-omitted control.

Ethanol is actively respired by this strain of *Chlorella*, giving a rate of uptake of oxygen in the Warburg flask of 24·7 μl./10^7 cells/hr. (averaged over 22 hr.) with 0·05 *M* ethanol as compared with 43·8 μl./10^7 cells/hr. with the optimum glucose concentration (0·028 *M*). With an initial population of 4 × 10^3 cells/mm.^{3} and 2·5 ml. suspending medium, the respiratory quotient with 0·02 per cent glucose remained at or slightly above 1·0 during a 24 hr. test although, due to sugar depletion, the rate of uptake of oxygen fell to a very low level by 18 hr. Addition at 12 hr. of ethanol to give a concentration of 0·08 per cent depressed the respiratory quotient during the period 12–24 hr. to give an average value of 0·35, and during the period 18–24 hr. the respiratory quotient was almost zero, oxygen uptake proceeding with almost no evolution of carbon dioxide.

Methanol is the only other alcohol, from a number that have been tested in our laboratory, which promotes growth and respiration when supplied as sole carbon source to our strain of *Chlorella*. It is of very low activity and promotion of growth and respiration only occurs over a narrow concentration range. Increase in number of cells over the control from which carbon was omitted was 3–4 per cent (0·025 *M* methanol) of that occurring in 1 per cent glucose, whereas ethanol supports growth-rates up to 75 per cent of those in glucose. In a direct comparison, the stimulation of uptake of oxygen was, with methanol (0·05 *M*) 16 per cent and with ethanol (0·05 *M*) 53 per cent of that in 0·028 *M* glucose.

A marked stimulation of growth from the addition of ethanol has also been observed with cultures of *Chlorella vulgaris*, Pratt, growing at 26° C. in inorganic medium and receiving at their under surface 350 lux from daylight fluorescent tubes. The culture vessels were 100 ml. wide-mouthed conical flasks. These contained 50 ml. medium, inoculated with 100 cells/mm.^{3}. 'Aerated' cultures received, in a fine stream of bubbles, about 20 ml./min. of a mixture of 95 per cent air and 5 per cent carbon dioxide for 1 hr. every 24 hr.; 'non-aerated' cultures were gently agitated once a day to disperse the cells. Under both experimental conditions ethanol stimulated growth (Table 4). The cell densities obtained in the 'aerated' cultures were much higher than could be achieved under the most favourable conditions of 'dark' culture adopted. The very great increase in cell number resulting in these 'aerated' cultures from the addition of 'ethanol' has not yet been examined in terms of carbon increase. Marked stimulation of growth could also be obtained by supplying glucose to these illuminated cultures.

Brannon[1] concluded that the ethanol introduced into his media was probably removed during autoclaving for 30 min. at 15 lb./in.^{2}. We have not reproduced Brannon's media but have found that our medium, containing initially 0·5 per cent ethanol, still gives a reaction for alcohol (assessed colorimetrically following oxidation to acetaldehyde with potassium bichromate–sulphuric acid) after autoclaving for 60 min. and that such media support, as a result of the ethanol addition, a significantly enhanced growth in illuminated 'non-aerated' cultures. These results not only raise the question of how far the presence of ethanol has been responsible for earlier reports of the stimulation of the growth of *Chlorella* by auxins but also suggest that the metabolism of ethanol in this organism should be the subject of further study.

A more detailed account of some of the results referred to here will be published elsewhere.

Effect of Heat Treatment on the Sintering of 'Active' Ceramic Oxide Powders

In recent years much attention has been paid to the preparation of 'active' oxide powders by decomposition of compounds; the oxide powders obtained in this way are agglomerates of fine crystallites, have high surface area and show enhanced sintering characteristics compared with the highly calcined powders normally used[1]. With pure powders prepared in this way, variations have been noted in the sintering behaviour which are difficult to account for.

It has now been found that in the sintering of compacts of these oxide powders, intermediate heat treatment at a temperature lower than the normal sintering temperature significantly increases the final bulk density. Two conditions are necessary to benefit from the effect: (1) The calcination of the original compound, such as the hydroxide before pressing, should be carried out at an optimum temperature, for example, with beryllium between 1,000° and 1,250° C. Compacts made from powder calcined at lower temperatures crack excessively on sintering, whereas the particle-size of powder calcined at higher temperatures is too large for appreciable densification to occur. (2) The pressed compact should be annealed at or near the calcination temperature of the powder and at successively higher temperatures to the temperature at which the rate of densification is high enough for the maximum bulk density to be reached in a reasonable time. In the annealing treatment, weld junctions are formed between the particles in contact in the pressed powder and the fine pore structure of the pressed compact is retained until the temperature is reached at which the rate of sintering becomes rapid. If the annealing treatment is omitted and the compact rapidly raised to the maximum temperature, uncontrolled shrinkage occurs within the agglomerate particles and these separate within the compact to form fissures and pores too large to be eliminated afterwards. The final bulk density is therefore much lower.

As an example, compacts made from beryllium oxide (BeO) prepared by calcining the hydroxide to 1,250° C. sinter to bulk densities of 2·2 gm./c.c. (that is, 27 per cent porosity) if rapidly heated to 1,600° C. in 1 hr. If similar compacts are heat-treated for several hours at 1,300–1,400° C. prior to the temperature being raised to 1,600° C., bulk densities of 2·75 gm./c.c. (that is, 8 per cent porosity) are obtained.

Confirmation of the hypothesis put forward to explain this effect has been obtained by applying an external pressure at high temperatures to the compact. Here the particles are prevented from separating at the points of contact by the external pressure, and high bulk densities result in all cases, independently of the heat treatment.

A fuller account of this work will be published elsewhere.

Investigation of the Ionosphere using Signals from Earth Satellites

I propose to discuss some possible effects of the ionosphere on the radio signals from artificial satellites on the basis of my theoretical results[1].

The occurrence of focusing of radio waves from the point antipodal to the observer could probably be demonstrated from measurements of Doppler frequency shift (Fig. 1*a* (i)). Let *O* denote the position of the observer, *S* the satellite, *Z* and *N* the points on the orbit of the satellite in the observer's zenith and nadir. Let the critical frequency f_c of the ionosphere increase from *Z* to *N*, where it attains a value slightly greater than the transmission frequency, f_0, of the satellite. Neglecting the presence of the Earth, the trajectories of ray paths and the corresponding Doppler curve are shown in Fig. 1*a* (i) and (ii), using dotted and continuous lines for the free-space and ionospherically propagated cases respectively. When the satellite moves from a typical point *K* to *N*, the frequency received via the free-space path increases slowly to the value f_0 transmitted by the satellite. In the ionospheric case, however, the frequency will remain nearly constant at a value f_K

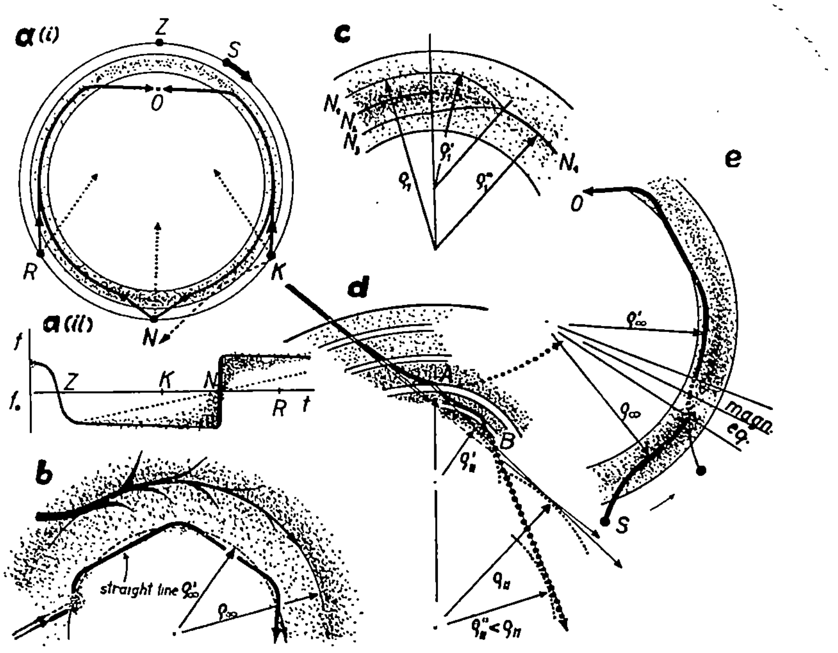

Fig. 1

until N is reached, after which the received frequency will rise suddenly to a value f_R, given by : $f_R - f_0 = f_0 - f_K$. In the vicinity of N, transmission of the signal over all possible great circle paths towards the antipodal point Z will occur. In this case all frequencies between f_K and f_R will be received. If reception occurred only within a narrower frequency band, this would indicate that propagation was effective only in a certain preferred range of directions. The maximum probability of multi-path propagation between S and O occurs when the satellite passes N.

Various theoretical modes of long-distance propagation around the Earth will now be discussed. It can be shown[2] that perpetual propagation of radio waves around the Earth in a conventional spherically symmetrical ionosphere is possible if :

$$\frac{d\mu}{d\rho} = -\frac{\mu}{\rho}$$

where μ denotes radio refractive index and ρ the radial distance. Provided the ionospheric critical frequency is smaller than the satellite frequency f_0, there usually exist two levels in the ionosphere which fulfil this condition. One of these critical levels, lying close below the maximum of electron density (denoted in Fig. 1*b* by ρ_∞), does not support stable propagation, since the smallest inhomogeneity of electron density will produce a considerable divergence of rays in all directions. The lower critical level (denoted by ρ'_∞) can support more stable propagation since small inhomogeneities will only cause the wave to oscillate along this critical level. On the other hand, to realize this desired propagation from S to O, there must always exist two suitable inhomogeneities, one to bring the ray from higher levels to this critical level and the second to take it down to the ground-level. The most probable mode of long-distance propagation seems to occur when a slight increase of electron density occurs along the ray path. Then a ray just passing the upper layer, but going so nearly tangentially that it cannot attain the surface of the Earth, can be trapped between the two levels. Let a further variation of altitude, electron density or thickness of the layer change the height of both reflecting levels (see the $\mu\rho$-diagram of ref. 2) ; when the lower one in effect falls to the surface of the Earth, the signal can be received.

Another mode of long-distance propagation by means of the ionosphere is possible, theoretically. Consider a layer the electron density of which decreases slightly in the horizontal (Fig. 1*a* (i) and *c*). Then an almost tangential ray, which in a layer with perfect spherical symmetry would usually be reflected, could pass farther into the ionosphere ; for a suitable decrease of f_c, long-distance propagation could then be realized. The penetration of the ray deeper into the ionosphere is best shown by reference to Fig. 1*d*. Suppose that the ionosphere is composed of a number of regions of finite thickness and uniform electron density separated by infinitesimally thin regions of zero electron density. According to ref. 1, so long as the layer traversed has perfect spherical symmetry and no horizontal variation, the ray is in the un-ionized regions tangential to the sphere designated by $\rho_\parallel$, concentric with the Earth's surface. At the point A, where the contour of constant electron density ceases to be spherical and decreases in radius of curvature, the ray must be tangential to a sphere of smaller radius $\rho'_\parallel$ in the intermediate un-ionized regions. Thus a ray approaching the ionosphere almost tangentially will not be reflected, but will pass through the layer very obliquely, covering a large horizontal distance.

Also the reported discrepancy[3] between the times of closest approach deduced from Doppler and direction-finding measurements might have other causes than an inclination to the horizontal of the lower boundary of the layer. It could be explained by an increase or decrease of the maximum electron density in some horizontal direction. The displacement of the centre of curvature of the contours of constant electron density from the plane of propagation could result in a considerable azimuthal deviation of the ray.

In long-distance propagation of satellite signals, an important part seems to be played by the deep local minimum of electron density usually present at the magnetic equator (Fig. 1*e*). The ray running along the ionosphere is bent slightly towards the Earth and after passing this electron density minimum is bent back to the horizontal direction. In this way it could easily attain even the stable 'critical level'. (Direct reflexions between Earth and ionosphere are not, in the early morning hours, very probable on 40 Mc./s. as the decrease of critical frequency towards the polar regions is usually very rapid, and the wave would pass through the ionosphere into space.)

Theoretically, all these modes of propagation from the antipodal point are thought to be possible on 40 Mc./s., although in practice none of them will appear frequently. A satisfactory answer to the question of what mode of propagation is preferred could probably be given by a detailed study of the Doppler curves, of direction-finding measurements and the variation of band-width of the received signal when the satellite is deep below the optical horizon.

Horizontal Drift Measurements in the Ionosphere near the Equator

MEASUREMENTS of horizontal drift in the ionospheric E- and F-layers have been made regularly at Ibadan (magnetic latitude 2½° S.) since June 1957. These measurements are of importance in view of the theory of the origin of such drifts put forward by Martyn[1]. According to this theory, a phase reversal of the east–west component of drifts in the F-region should occur at latitudes 35° N. and 35° S. Confirmation of this phase reversal has been obtained by Purslow[2] and Rao and Rao[3] at Singapore and Waltair (India) respectively. Martyn's theory further predicts that at the magnetic equator the westward drift in the F-layer during the daytime should be of the order 200 m./sec., about twice that obtained in temperate latitudes.

The method used to measure horizontal drifts at Ibadan is similar in principle to that originated by Mitra[4], using a pulse transmitter and three spaced receiving aerials. The aerials are half-wave dipoles at 2·4 Mc./s. and are spaced at the corners of a right-angled triangle with its hypotenuse in the magnetic north–south plane, and with sides of length 127 m., 127 m. and 180 m. A film speed of about 20 cm./min.

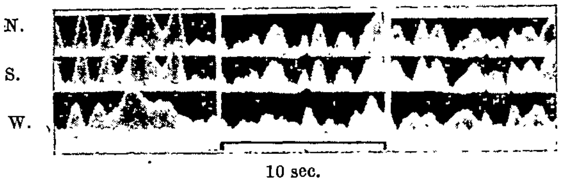

Fig. 1. Sample drift record

is normally used, and a typical film record obtained is shown in Fig. 1. E-layer drifts are measured using a frequency of 2·4 Mc./s. and F-layer drifts with a frequency of 5·7 Mc./s.

The normal method of analysis of drift records consists in measuring time-shifts between pairs of records. A simple calculation then yields the drift velocity. It is assumed in this method that the amplitude pattern on the ground remains constant in detail as it moves and that it is statistically isometric so that its statistical properties show circular symmetry. If the second assumption is not true, considerable error will arise in the apparent direction of the drift.

It is seen in Fig. 1 that at Ibadan the amplitude-fading records for the north and south aerials are almost identical and that there is no measurable time-shift between them. The record from the west aerial is similar in form but displaced in time relative to those from the north and south aerials. This strongly suggests that the amplitude pattern on the ground is elongated in the north–south direction, and an analysis of the type developed by Phillips and Spencer[5] has been made on representative records. Phillips and Spencer showed that an amplitude pattern in which the irregularities are on the average anisometric can be represented to a first approximation by a 'characteristic ellipse' representing a contour of equal auto-correlation. The axial ratio and angle of orientation of this ellipse can be obtained by a laborious process involving the calculation of the cross-correlation functions between the different pairs of aerials. This calculation is best done by means of an electronic computer, and we are indebted to the Cavendish Laboratory, Cambridge, for the analysis of certain records using the EDSAC. Other records have been separately analysed by one of us (J. H.) and the results of both analyses are summarized in Table 1.

Table 1

Layer	Mean axial ratio	Mean angle of orientation of major axis in deg. E. of magnetic N.	No. of records analysed
E	5	0°	24
F	11	0°	24

The orientations of the major axes of the ellipses are almost without exception within a few degrees of magnetic north–south and the mean orientation for both E- and F-layers is less than one degree from the magnetic meridian. There is evidence that the anisometry is more pronounced in the F-layer than in the E-layer, the mean axial ratios of the characteristic ellipses being 11 and 5 respectively. However, the values are widely distributed and, with the limited number of values at present available, no great significance should be attached to the actual values 11 and 5.

Comparable results are rather scarce and somewhat contradictory. Spencer[6], at Cambridge, using a radio stellar technique, has reported the presence of irregularities in the F-layer elongated by a factor of at least 5 : 1 along the Earth's magnetic lines of force. Phillips and Spencer[5], however, found that the axial ratios were usually less than 1·5 in the E- and F-layers for the cases that they examined using the pulse reflexion method. They also found that there was no preferred direction for the axes of the ellipses. Purslow states in a private communication that, at Singapore, axial ratios of about 2 : 1 are obtained. It is difficult to reconcile this large difference between the results at Singapore and Ibadan, which are stations of similar latitude.

The effect of the north–south elongation of the amplitude pattern is to mask the meridional components of drift. The true direction of drift can be obtained from the full correlation analysis, but this is a laborious process even with the aid of a computing machine. The east–west component, however, can be obtained from a consideration of time shifts between the fading records at the north–south and west aerials. Results have been analysed in this way for about 25 complete days in August and September 1957. Figs. 2a and 2b show the mean diurnal variation of the east–west component of the drift velocities in the E- and F-layers respectively. It is seen that in both layers the drift is towards the west during the daytime and towards the east at night, in agreement with the predictions of Martyn's theory, and in opposite phase to that found in temperate latitudes. Harmonic analysis of the F-layer data brings out the predominant 24-hr. period component. It is found that the east–west velocity, $V_{E\text{-}W}$, can be represented by the function:

$$V_{E\text{-}W} = -10{\cdot}5 + 111\sin(t + 68^\circ) + 26\sin(2t + 54^\circ) \quad \text{(m./sec.)}.$$

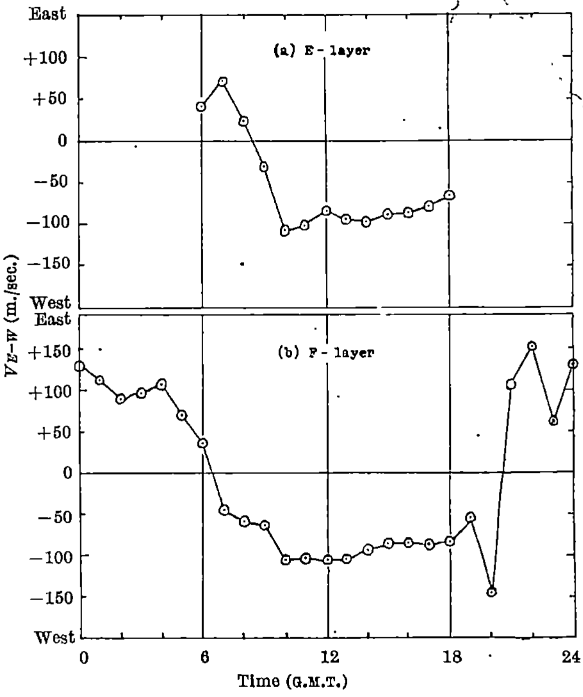

Fig. 2. Diurnal variation of east–west drift component (a) in the E-layer and (b) in the F-layer

This may be compared with Purslow's results[2] for Singapore, and Rao and Rao[3] for Waltair:

$$V_{E\text{-}W} = 1\cdot 7 + 88\sin(t + 59^\circ) + 3\sin(2t + 210)$$
(m./sec.) Waltair (autumn).

$$V_{E\text{-}W} = 18 + 45\sin(t + 84^\circ) + 22\sin(2t + 38^\circ)$$
(m./sec.) Singapore.

It is seen that the phases of the 24-hr. components are similar at the three stations although there is considerable variation in the amplitudes.

The westward daytime drift velocity in the F-layer of about 105 m./sec. at Ibadan is smaller than that predicted by Martyn (200 m./sec.), but it should be remembered that Ibadan is not placed directly beneath the centre of the equatorial 'electrojet' current. The velocity at Ibadan is larger than those at Singapore and Waltair, which are themselves farther from the magnetic equator. It is quite possible that larger velocities would be obtained at stations a few hundred kilometres north of Ibadan.

A Man-made or Artifical Aurora

At 1051 G.M.T. on August 1, 1958, Mr. J. G. Keys, observer-in-charge at Apia Observatory, latitude 13° 48′ S., longitude 171° 46′ W., witnessed at Apia a manifestation which was at first thought to be a display of the aurora australis but is now believed to be due to a nuclear bomb explosion in the upper atmosphere. The occurrence of an auroral display in the tropics is always of unusual interest to geophysicists because of its exceeding rarity. In particular, the Aurora Australis has been reported at Apia on one occasion only, and then only in association with the severe magnetic storm of May 13–16, 1921. This display was described in detail by Angenheister[1] and Angenheister and Westland[2].

The display seen by Keys is of more than usual interest because of the extraordinary effects associated with it. Briefly, his description of the manifestation is as follows.

The display was first observed on August 1 at 1051 G.M.T. with bright rays in the western sky extending from bearing 235° and bearing 286° where the altitude of the rays was 12°. On the bearing of 235° the rays disappeared behind coconut trees at an altitude of 10·5°. It is inferred that the rays extended towards the southerly horizon. This manifestation persisted for about 6 min., then gradually diminished to a red glow centred on a bearing of 247°. This glow faded completely at 1105 G.M.T. The rays were at first violet, covered with reds and gradually changed to greens. There was a crimson arc with centre elevation 32° on a bearing of 340° and this gradually faded. Three or four red bands were seen with their centres approximately due south at an elevation of about 30–40°, and these faded rapidly. The night sky was clear with one-eighth cumulus cloud at 2,500 ft., and the moon was just past full. Associated with these manifestations were radio fade-outs which lasted from one to several hours.

Keys noticed a most unusual pronounced sudden commencement on the Apia normal and rapid run magnetograms covering the time of the above described manifestation, and sent copies to me. At 1050 G.M.T. the Apia magnetograms showed pronounced sudden commencement with reverse impulse *ssc**, and for the 3-hr. period 0900–1200 G.M.T. the K-index was 6. The Amberley (latitude 43° 09′ S., longitude 172° 43′ E.) magnetograms show no extraordinary effects and in particular no sudden commencement with or without reverse impulse.

The sudden commencement recorded at Apia is itself most unusual because of its form, which was similar to that which one would expect at a high-latitude station near the auroral zone, and not its usual simple form. The occurrence of sudden commencements with reverse impulse *ssc** is comparatively rare at Apia, and when they do occur the reverse impulse has a very small amplitude. In this case, the reverse amplitude was comparatively large and well defined. The sudden commencement in the D trace at Apia is usually very small, seldom exceeding a minute or two. In this case the amplitude of the sudden commencement in D was 9 min. The magnetic disturbance lasted about an hour and seems to have been superposed on a minor bay disturbance which was already in progress before the sudden commencement.

Auroræ, when seen in tropical regions, have always been associated with severe world-wide magnetic storms. The Amberley magnetograms show that at the time in question there was no severe magnetic storm in progress except a bay type of disturbance with K-index 3. A comparison of the Amberley and Apia magnetograms shows definitely that the magnetic disturbance recorded at Apia was not world-wide but appeared to be localized in the Central Pacific area.

If an aurora australis had been seen at Apia it should have been seen low down in the southern sky. In the manifestation described above, rays were seen in the western sky and a crimson arc was seen at an altitude of 32° in the northern sky. It was unlikely that the manifestation was the aurora borealis because Apia lies well to the south of the equator and no world-wide severe magnetic storm was in progress.

The abnormal directions in which the manifestations were seen, as well as the abnormal magnetic effects recorded at Apia, point to the fact that it was not a normal auroral display.

Approximately at the time of the sudden commencement recorded at Apia, American scientists exploded a nuclear bomb high in the upper atmosphere, at a height of 100 miles according to newspaper reports—over Johnston Island. There seems to be little doubt that the unusual magnetic effects recorded at Apia are related to this explosion and that the manifestation seen at Apia was a man-made or artificial aurora due to a nuclear explosion in the upper atmosphere.

A study of the effects due to this explosion may throw considerable light on the theory of magnetic storms and auroræ. It would be of great interest to know whether other magnetic stations in the

Central Pacific recorded similar abnormal magnetic effects.

Emission Spectrum of N_2O+

IN the course of a study of the luminescence of gases irradiated by X-rays (to be published), some unknown bands were observed from nitrous oxide. All the other gases studied emit well-known band systems, usually of the parent gas or its ion. Gases at pressures between 1 and 700 mm. were irradiated with soft X-rays (45 kV. peak) from a beryllium-window tube, and the spectra photographed or scanned with a photomultiplier through a Hilger *D*.96 *f* 2 quartz spectrograph. The emission from nitrous oxide consisted of the unknown bands at about 3680, 3540 and 3380 A. and the nitric oxide β system (the bands in the $v' = 0$ progression between $v'' = 3$ and 13 were observed). The latter system has been observed previously as fluorescence from nitrous oxide irradiated with vacuum ultra-violet light[1]. The two sets of bands differ in their dependence on pressure; the β bands suffer little collisional deactivation at high pressures whereas the new bands are strongly 'quenched', but they must be much more strongly excited since the intensities are roughly comparable at 600 mm. Since carbon dioxide excited by X-rays emits CO_2+ bands ($^2\Sigma_u - {}^2\Pi_g$, ref. 2, and $^2\Pi_u - {}^2\Pi_g$, ref. 3) and these show a similar pressure dependence, the new bands are tentatively ascribed to N_2O+. Emission by nitrous oxide (N_2O) itself is unlikely from a consideration of its excited states[4].

The observed light intensity was very small (8-hr. exposures with $\frac{1}{2}$ mm. slit-width were necessary to photograph the spectra on *HPS* plates) and the dispersion low (100 A./mm. at 3500 A.) so the bands could not be properly characterized with this apparatus. Therefore an attempt to excite the bands in a discharge tube was made. If the identification is correct, they should appear in the negative glow; low current density and rapid flow of the gas would be necessary to reduce the decomposition of nitrous oxide which occurs in the discharge.

The discharge tube was a T-shaped 'Pyrex' tube, with $\frac{3}{4}$ in. internal diameter, 2 in. long aluminium tube as cathode and a smaller aluminium tube in a side-arm as anode; nitrous oxide was pumped through the tube from cathode to anode; spectra were photographed through a silica window with a Hilger medium quartz spectrograph. The positive column in the side tube was coloured green or pink (first positive bands of molecular nitrogen); the cathode glow was blue. The new bands appeared in the cathode glow and behaved as expected. A detailed study of the excitation conditions was not made, but the best conditions seemed to be 1 mm. mercury pressure and minimum discharge current (8 m.amp.). The bands also appeared at higher pressures (3–4 mm.); though more current was needed (50 m.amp.), the flow rate was probably higher. The nitrogen second positive and first negative systems and the nitric oxide β and γ systems were also present; the nitrogen bands were of comparable intensity with the new bands and may have obscured some of them. A better separation from these emissions from decomposition products of nitrous oxide would probably be obtained at higher rates of flow.

Table 1. WAVE-LENGTHS AND INTENSITIES OF THE NEW BAND SYSTEM

(A.)	I	(A.)	I	(A.)	I
3380	*S*	3595	*MS*	3773	*WM*
3396	*S*	3611	*M*	3823	*M*
3429	*W*	3626	*W*	3843	*S*
3434	*W*	3636	*WM*	3864	*S*
3454	*MS*	3653	*MS*	3874	*W*
3470	*MS*	3661	*M*	3928	*W*
3481	*W*	3673	*MS*	3961	*W*
3493	*M*	3687	*VS*	3981	*W*
3516	*MS*	3706	*VS*	4008	*WM*
3521	*M*	3720	*W*	4030	*WM*
3541	*VS*	3746	*MS*	4126	*W*
3558	*VS*	3764	*WM*	4225	*W*

The band heads and estimated intensities are listed in Table 1. A number of very weak bands were also observed and probably belong to this system; the strong bands were clearly degraded to the violet. Though further evidence is required, the most likely emitter of these bands seems to be N_2O+. Further study of them would be of interest for comparison with the isoelectronic CO_2+ (refs. 2 and 3) and NCO (ref. 5).

I wish to thank the U.K. Atomic Energy Authority for a research fellowship, during the tenure of which this work was carried out.

Abnormally High Fatigue Strengths in Aluminium Alloy Extruded Bar

IN 1932, Matthaes[1] reported that the tension properties of aluminium alloy extrusions in the longitudinal direction were significantly greater than in the transverse direction, and it is now well known that both the ultimate tensile stress and proof stress values may be 20–30 per cent greater than the respective values for rolled or forged material. However, it has been observed[2] that the fatigue properties are little affected by the extrusion process. In view of this the following results are of interest.

Unnotched and notched rotating cantilever fatigue tests at 12,000 cycles/min. have been conducted on two batches of aluminium alloy extruded bar, one of 0·510 in. diameter to specification *S.A.A.*(*E*)2*D*.649 (24*S*-*T*) and the other of 0·750 in. diameter to specification *D.T.D*.683/3 (75*S*-*T*), both batches being of Australian manufacture.

Table 1 shows that the tension properties of both batches are far in excess of the specification properties for these alloys. Fatigue tests using specimens of 0·300 in. nominal test diameter have indicated that the materials exhibit several unusual characteristics.

In Fig. 1 are shown the mean *S*–*N* curves for specimens of the 24*S*-*T* material; these are also typical of

Table 1. TENSION PROPERTIES OF THE EXTRUDED ALLOYS

	0·1 per cent proof stress (lb./sq. in.)	0·2 per cent proof stress (lb./sq. in.)	Ultimate tensile strength (lb./sq. in.)	Elongation (per cent)	Hardness (B.H.N.)
Spec. *S.A.A.(E)2D.*649 (minimum)	38,000	40,000	63,000	12	—
(as received)	60,000	62,000	86,000	13·5	141
24*S–T*4 (typical)	—	49,000	69,000	18	120
Spec. *D.T.D.*683/3 (minimum)	67,250	—	78,500	7	—
(as received)	81,500	83,750	93,000	8	172
*D.T.D.*683 (typical)	82,500	—	90,000	10·5	170

the *D.T.D.*683. The unnotched curve was obtained using specimens finished by diamond turning, while the notched specimens were machined by plunge cutting with a form tool. Notch radius was 0·080 in., giving a theoretical stress concentration factor of approximately 1·5. For these materials the unnotched fatigue strengths at 10^8 cycles are about 50 and 80 per cent greater respectively than typical values quoted for the two alloys, that is, approximately 30,000 lb./sq. in. compared with 20,000 lb./sq. in. for the 24*S-T* and approximately 42,000 lb./sq. in. compared with 23,000 lb./sq. in. in the case of the *D.T.D.*683.

Fig. 1 also shows that the notched fatigue strength at 10^8 cycles (approximately 25,000 lb./sq. in. for each alloy) is likewise higher than might be expected, but more remarkable is the unusual shape of the curve. Notched specimens, particularly those tested at high nominal stresses, tended to give a 'conical' type of fracture, a good example of which is shown in Fig. 2. This type of fracture is similar to that reported by Vitovec[3] after applying a high static preload to a notched fatigue specimen.

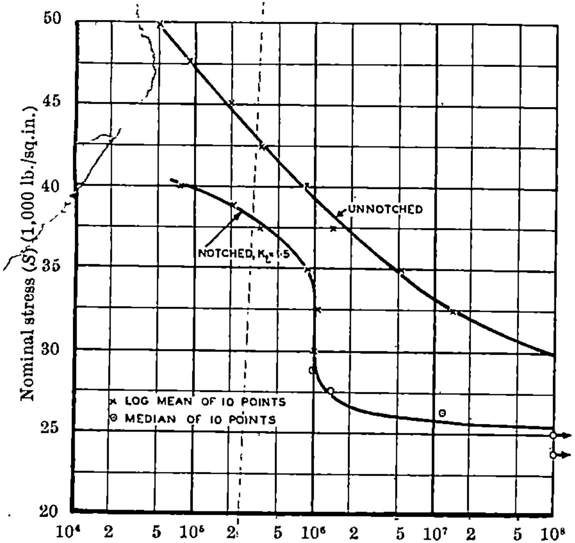

Fig. 1. Fatigue curves for 24*S-T* aluminium alloy

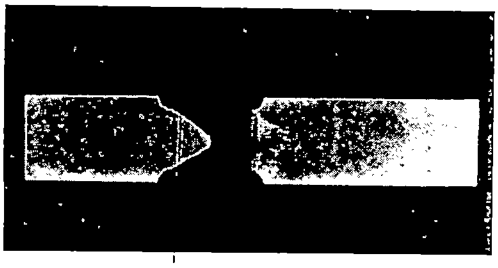

Fig. 2. Longitudinal section through fractured 24*S-T* notched fatigue specimen, radius 0·080 in.

Metallographic examination of the alloys has indicated a marked directionality effect along the length of the bars, but at this stage no other unusual characteristics have been observed.

A possible explanation is that the abnormal characteristics in these materials may be associated with some peculiar extrusion texture, and that this has caused significant modifications in the mode of precipitation in the alloys. In view of the practical implications of the high properties observed, it is intended to make a more detailed investigation of these materials.

This work forms part of a programme on the fatigue of aircraft materials being conducted at the Aeronautical Research Laboratories in Melbourne. Acknowledgment is made to the Chief Scientist, Australian Defence Scientific Service, Department of Supply, Melbourne, Australia, for permission to publish this communication.

A Phosphatic Band underlying Bauxite Deposits in Jamaica

IN 1957, during a detailed examination of the bauxite deposits in Jamaica, suggested by Dr. D. A. Bryn Davies, managing director of Alumina Jamaica, Ltd., and sponsored by that Company, I noticed the occurrence of a hitherto unrecorded sedimentary band separating red bauxite from underlying white Tertiary limestones. The band is extremely local in occurrence. So far as at present known, it is only typically developed within a limited area around the Kirkvine Works of Alumina Jamaica, near Mandeville, and at Grove Place, about 4 miles to the north-west. It is known to be absent in many other areas. It has, however, certain interesting characteristics which may have some bearing on the history and age of the bauxite deposits. For this reason, and because it may lead to the recording of other occurrences in Jamaica, or even in association with the similar bauxite deposits in Haiti and the Dominican Republic, it seems worth placing on record the following summary account. It is intended to include a more detailed description in a later general account of the bauxite deposits.

In nearly all the occurrences examined, the band was found to be very thin and inconspicuous. It seldom exceeds one foot in thickness, and it is often only one inch or less thick. It tends to be lenticular in habit, and is discontinuous within the limited area in which it has so far been recognized. In spite of its thinness, it may include several layers or laminæ differing in composition, or in appearance.

As a whole, the band has the following distinctive chemical characteristics:

(1) It is often highly phosphatic, some layers consisting almost entirely of white collophane.

(2) Spectrographic examinations carried out by Aluminium Laboratories, Ltd., at Arvida, Quebec; by Mr. C. O. Harvey, in the Chemical Laboratories of the Geological Survey, London; and, at the suggestion of Dr. A. Muir, in the laboratories of the Soil Survey Division, Rothamsted Experimental Station, Harpenden, England, disclosed the presence of a considerable number of rare or uncommon elements, including silver, barium, beryllium, cadmium, cobalt, chromium, copper, nickel, lead, strontium, tin, yttrium, zinc and zirconium. While most of these are present only in minor or very minor amounts, some, notably zinc, cadmium, beryllium and yttrium, were found to be present in surprisingly high concentrations in certain samples.

(3) The band is radioactive to an extent appreciably greater than the overlying bauxite. Determinations made in the laboratories of the Atomic Energy Division of the Geological Survey, London, on ten different samples of sediment gave results indicating a content of radioactive matter ranging from 0·006 to 0·028 (average 0·0145) per cent U_3O_8 equivalent, that is, quantitatively, the radiation detected is equivalent to that which would be emitted if the stated amount of U_3O_8 were present in the rock, to the exclusion of other radioactive elements. No attempt has been made as yet to determine what element or elements cause the radiation. Mr. S. H. U. Bowie, chief geologist of the Division, informs me that the figures obtained by his staff during a survey of radioactivity in Jamaica indicate the radioactivity of the bauxite to be about one-twentieth of that of the most active of the phosphatic sediments.

A further characteristic of the phosphatic band is that it is fossiliferous, the organic remains consisting almost entirely of very small (< 10 mm.) fish teeth. A large collection of these teeth was submitted to Dr. E. I. White, keeper of palæontology in the British Museum (Natural History), who states that the assemblage is definitely marine, and includes teeth of small carcharinid sharks, chaetodonts, sparids, labrids (wrasse) and scarids; but it is not possible on the basis of the material submitted to assign a more definite age than Tertiary (or later) to the assemblage.

It may be added that a few specimens of teeth were tested for radioactivity, and gave a result indicating 0·008 per cent U_3O_8 equivalent.

The above characteristics of the sedimentary band, taken as a whole, suggest that it should be classified as a marine phosphorite, comparable in general character with, for example, the marine phosphorites of the Bone Valley formation in Florida. If this comparison can be sustained, the Jamaican deposits probably represent the attenuated and re-sorted remnants of a once more extensive phosphorite deposit, younger than the karstified white limestones (Upper Eocene to Lower Miocene) on which it rests. Deposition may have taken place during the submergence of Jamaica in Plio-Pleistocene time. I have seen evidence of submergence at heights at least 1,500 ft. above present sea-level, and Butterlin[1] records marine terraces in Haiti up to a height exceeding 2,000 ft. (630 metres).

A further point of interest is that the known occurrences of the phosphatic sedimentary band lie on the margin of an area within which there are several deposits of bauxite with an abnormally high phosphate content. The evidence so far available, however, is insufficient to determine whether or not there is any interdependence between the occurrences of phosphatic sediment and the distribution of high-phosphate bauxite.

Electron Transfer and Thermal Racemization of Ethylenediaminetetraacetato-cobaltate(III)

IN general, electron-transfer reactions which involve no net chemical change have been studied by the use of isotopic tracers. In 1950, Dwyer and Gyarfas[1] reported that the mixing of *d*-tris(2,2′-bipyridine)-osmium(II) with *l*-tris(2,2′-bipyridine)osmium(III) was followed by the very rapid loss of all optical activity. This was explained by assuming that a rapid electron transfer process led to redistribution of the dextro and lævo configurations among the two oxidation states. Consequently, Dwyer and Gyarfas suggested that optical activity should pro- vide a second convenient method for the study the kinetics of electron-transfer processes.

Prior to the investigations reported in th munication, systems of this type which h examined were found to be either too rapid detailed study[2], or very poorly reproducibl D. H., and Stratton, W. J., unpublished re

The system:

$$[\text{Co-III (EDTA)}]^- - [\text{Co-II (EDTA)}]$$

has been found convenient for the detailed s electron transfer by means of optical activit ceeding at an easily measured rate, wit reproducibility. Adamson and Vorres[3] inve isotopic transfer in this system, and the co complex has been resolved into its optical antipo (Dwyer, F. P., private communication, provides best method of resolution). Since the cobalt(II) complex is configurationally unstable, electron transfer should be accompanied by racemization, as indicated in the following equation:

$$d\text{-}[\text{Co-III (EDTA)}]^- + [\text{Co-II (EDTA)}]^{2-} \rightleftharpoons [\text{Co-II (EDTA)}]^{2-} + l\text{-}[\text{Co-III (EDTA)}]^-$$

Although *d*-$[\text{Co-III (EDTA)}]^-$ is optically stable at room temperature, it does racemize[5] at 100° C. Consequently, a second path for racemization might be observed in accordance with the equation:

$$d\text{-}[\text{Co-III (EDTA)}]^- \rightleftharpoons l\text{-}[\text{Co-III (EDTA)}]^-$$

Reproducible results have been obtained indicating that the hexadentate complex *d*-$[\text{Co-III (EDTA)}]^-$

undergoes racemization at 100° C., and that this racemization process is catalysed by the cobalt(II) complex. The concentrations of the cobalt(III) complex and of the cobalt(II) complex have been varied, as has the ionic strength. The pH was maintained in the region $2{\cdot}0 \pm 0{\cdot}2$. The expected pseudo-first-order kinetics in rotation were observed in accordance with the expression:

$$-\ln(\alpha/\alpha_0) = Rt$$

where α is the rotation at any time t, α_0 is the rotation at zero time, and R is the pseudo-first-order rate constant.

The integrated rate law accounting for these two paths is:

$$-\ln(\alpha/\alpha_0) = 2(kb + k')t$$

where k is the second-order constant associated with electron-transfer process, k' is the rate constant for thermal racemization, and b is the concentration of [Co-II (EDTA)]$^{2-}$. Equating coefficients of t in the experimental and theoretical rate equations gives the equation:

$$R = 2kb + 2k'$$

From the linear dependence of R on b, k and k' are [illegible]ted to be $1{\cdot}4\ M^{-1}$hr.$^{-1}$ and $0{\cdot}015$ hr.$^{-1}$, re[illegible]y. Direct determination of k' also gives an [illegible]value of $0{\cdot}015$ hr.$^{-1}$ for five experiments [illegible] zero concentration of cobalt(II) complex. [illegible]ults reported by Adamson and Vorres[3] were [illegible]d at 60°, 70° and 85° C. Extrapolation of [illegible] 100° C. gives $2{\cdot}1\ M^{-1}$hr.$^{-1}$ as the value [illegible]cond-order rate constant. It can be shown [illegible] defined here, corresponds to one-half the [illegible]ived from the McKay equation for electron [illegible]sotopic method). Consequently, the value [illegible] here ($1{\cdot}4\ M^{-1}$hr.$^{-1}$) should be compared [illegible]alf the value reported by Adamson and [illegible]amely, $1{\cdot}1\ M^{-1}$hr.$^{-1}$. These studies will be [illegible]d in greater detail at a later date.

[illegible]pport of this research by the National Science [illegible]ndation, Washington 25, D.C., is gratefully [illegible]knowledged.

Electronic Configuration d^4 in a Complex Ion

BECAUSE of the instability of the valence states which transition metal atoms must possess in order to have four non-bonding electrons remaining after forming a d^2sp^3 octahedral complex ion, few simple ions of this configuration have been studied. This lack of experimental data has seriously hindered the elucidation of the properties to be expected for a complex ion of this type[1].

In this laboratory we have recently measured the magnetic susceptibilities of the potassium hexahalo-osmates-IV, K_2OsF_6, K_2OsCl_6 and K_2OsBr_6, and recorded their ultra-violet and visible spectra (200–750 mμ) and their infra-red spectra (2–33μ). Johannesan and Lindberg[2] previously reported that $(NH_4)_2OsBr_6$ exhibited a paramagnetism independent of temperature which they explained on the basis of Kotani's[3] theory of spin-orbit coupling. Nyholm *et al.*[4] have recently shown that the same ideas can be applied to K_2OsCl_6. In both the above cases, a reasonably good agreement with theory is obtained for the magnetic properties of these compounds, if one invokes a rather large amount of spin-orbit coupling, $A = 6{,}400$ cm.$^{-1}$.

We have found that this large amount of spin-orbit coupling will also explain the observed visible spectra for K_2OsCl_6 and K_2OsBr_6 when the predictions of Kotani's theory are combined with certain results from ligand field theory.

In Kotani's theory the spatial degeneracy of the three t_{2g} orbitals is removed, and the resulting levels have energies $-A/2$, $-A$, and $A/2$ cm.$^{-1}$ respectively. If one considers transitions from these 'perturbed' levels to an anti-bonding e^*_g orbital, the counterpart of the bonding molecular orbital constructed from the d_{e_g} orbital of metal atom and the e_g orbital of the ligand, a reasonable explanation of the absorption spectra results. One finds peaks which differ in energies by approximately the amounts which the t_{2g} orbitals are perturbed via spin-orbit coupling. The energy difference between the lowest t_{2g} orbital and the e^*_g orbital (10 Dq) decreases regularly from $OsF_6^{=}$ to $OsBr_6^{=}$, as one would predict due to the decreasing strength of the crystal fields.

Unfortunately, the magnetic results obtained for K_2OsF_6 do not fit a Kotani-type curve, and hence it is difficult to evaluate the spin-orbit coupling constant. It is interesting to note that the visible spectrum of this material differs markedly from that of the others, containing only two bands, one at 50,000 cm.$^{-1}$ and one at 32,467 cm.$^{-1}$ [5], and also that this material is a light yellow compound while K_2OsCl_6 (wine-red) and K_2OsBr_6 (black) are both deeply coloured materials.

It would be interesting to see if other complex ions of the heavier transition metal atoms possess an absorption spectrum which can be explained by the utilization of the spin-orbit coupling concept. These three materials, together with $(NH_4)_2OsBr_6$, are (to our knowledge) the only known examples of paramagnetic substances independent of temperature among the complex ions of the platinum group elements.

The details of the above work and a more complete discussion of the theoretical aspects of the problem will be published soon.

We would like to acknowledge the many helpful discussions with Dr. James Richardson and Dr. J. M. Honig. One of us (A. G. T.) wishes to acknowledge the financial assistance of the Purdue Research Foundation and the Research Corporation for the years 1956 and 1957.

An Anodal Threshold Phenomenon in the Squid Giant Axon

The action potential of nerve or muscle is an all-or-none response when preceded by a critical decrease in transmembrane potential. Previous investigations[1-3], on the other hand, have indicated that for hyperpolarization by anodal (inward) currents the membrane's properties are a continuous function of current. I wish to report, however, that in a potassium-enriched medium the squid giant axon displays a discontinuous rise in membrane potential for a sufficiently intense anodal current and that this behaviour is, in several respects, similar to that of the action potential.

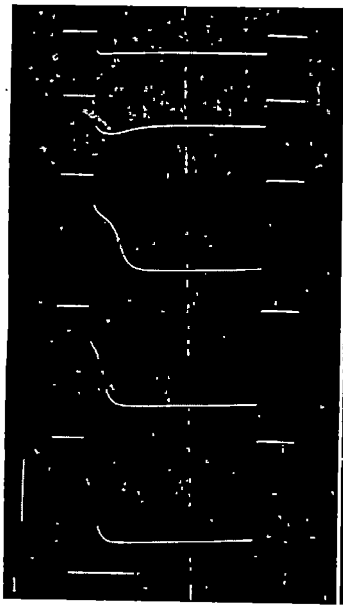

Fig. 1. Changes in transmembrane potential associated with increasing intensities of anodal current. Reading from top to bottom, the current densities (m.amp./cm.^{2}) are 0·079, 0·110, 0·115, 0·120, 0·126, respectively. The vertical and horizontal bars subtend 50 mV. and 50 msec., respectively. Axon No. 1 ; temperature, 21° C.

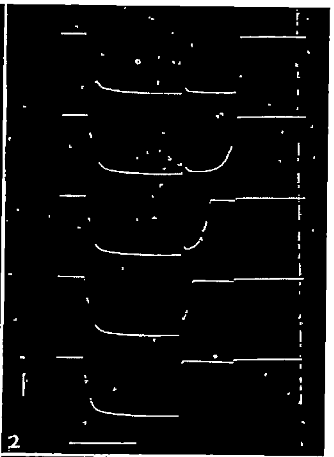

Fig. 2. Application of short cathodal pulses of increasing (top to bottom) intensities during a suprathreshold response. The vertical and horizontal bars subtend 50 mV. and 50 msec., respectively. Axon No. 2 ; temperature, 22° C.

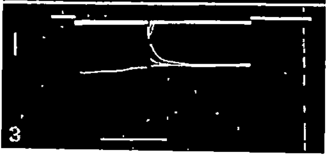

Fig. 3. Composite record made during repetition (1/sec.) of 130 msec. anodal pulse superposed upon which is a brief anodal pulse (see text for details). The vertical and horizontal bars subtend 50 mV. and 50 msec., respectively. Axon No. 3 ; temperature, 21° C.

The present results were obtained from axons immersed in a solution of 400 mM potassium acetate, 0·6 mM potassium bicarbonate, and sufficient sucrose to maintain tonicity. Fig. 1 shows the change in transmembrane potential recorded at the midpoint of a 17-mm. length of axon across the membrane of which pulses of various intensities of anodal current were passed. A graph of steady-state potential as a function of current consists of two distinct straight lines both extrapolating close to the origin, indicating that for the present medium the threshold change is a discrete decrease in membrane conductance (in the case illustrated the ratio is 0·29 : 1). A long relative refractory period (associated with an increase in conductance relative to that of the resting membrane) follows the 'excited' state : repetitition of the same pulse within a period of less than 1½ min. fails to elicit the suprathreshold response (there is no such refractoriness for subthreshold currents).

That this response represents a discontinuity in the current-voltage (I–V) relationship (when examined with pulses of constant current) and not merely a region of high dV/dI is illustrated by Figs. 2 and 3, in which short cathodal and anodal pulses, respectively, superimposed on the main response, are compared.

It can be seen that following the cathodal pulse the potential is stable at only one of two levels—the transition zone is 'forbidden'. (For cathodal currents the steady-state I–V curve contains no discontinuity and it is not possible to abolish a maintained depolarization with a short anodal pulse.) An analogous phenomenon for the normal threshold response (abolition by application of short anodal pulses during the action potential) has been described for the node of Ranvier[4], for the squid axon injected with tetraethylammonium chloride[5], and for cardiac muscle[6].

The converse property is demonstrated by the experiment of Fig. 3, which shows (in a composite record of approximately ten traces) the effect of the repetition (1/sec.) of a 1-msec. anodal pulse superposed midway during a 130-msec. anodal pulse (both [illegible] were of approximately the same inten[illegible] were not altered during the tra[illegible] largest prolonged downward deflex[illegible] potential recorded during the appli[illegible] the first pulse of the sequence. Th[illegible] prolonged deflexion is the response [illegible] of the next five pulses—the system [illegible] tory. As the refractoriness sub[illegible] short pulse becomes adequate to elic[illegible] the remainder of the long pulse) [illegible] threshold response as indicated b[illegible] traces with slow rising phases fol[illegible] end of the short pulse. This, agai[illegible] strates that the potential cannot be st[illegible] in the region between the sub- and s[illegible] threshold levels.

A sufficient condition for the abo[illegible] phenomenon is a concentration of potassium greater than normal irrespective of the presence or absence of calcium, sodium, or of chloride.

I am indebted to Dr. I. Tasaki for his provision of laboratory space and for the loan of some equipment. I thank Mrs. I. Tasaki for constructing the electrodes employed in this investigation.

Formation of Condensed Tannins in Plants

I have presented evidence[1] that leucoanthocyanins are probable precursors of condensed tannins ; recent examination of *Schinopsis* spp.[2,3] supports this view (see also ref. 4). It was shown[1] that most of the soluble phenolic materials in the sapwood of *Eucalyptus marginata* were leucoanthocyanins, and that the amount increased at the sapwood–heartwood boundary, where they were changed into the insoluble 'tannins' characteristic of this species. In some samples containing a distinctive outer heartwood zone, this change in solubility was found to be incomplete. Monomeric leucoanthocyanins which yielded delphinidin and cyanidin were found in this zone but were not observed in the inner heartwood.

When the ray and vertical parenchyma cells die at the sapwood–heartwood boundary, increased amounts of tannins appear and are liberated into the surrounding tissues. It is significant, therefore, that the ray parenchyma cells only of Douglas fir contain leucoanthocyanins[5]. This conclusion was drawn from the observation that the contents of these cells rapidly became red on the addition of concentrated hydrochloric acid. However, all the leucoanthocyanins we tested failed to behave in this manner.

We have found that the leucoanthocyanins can be made insoluble if blocks of fresh wood (*Eucalyptus* spp.) are soaked in a mixture of 40 per cent formalin/glacial acetic acid/water (5 : 15 : 80) under vacuum for 18 hr., heated for 1 hr., then boiled in water for 3 hr. When sections from these blocks were heated with butanol/hydrochloric acid (20 : 1) for 40 min., little, or no, formation of alcohol-soluble anthocyanidins occurred. After the sections were mounted in glycerol/water/hydrochloric acid (47 : 47 : 6) the contents of the parenchyma tissue in the sapwood were observed to be bright red ; but no evidence of diffusion into the surrounding tissue was seen. Because anthocyanidins were obtained from untreated specimens, and as leucoanthocyanins are almost the only compounds which become red after heating with hydrochloric acid, the colour formed in the treated sections is considered to be due to leucoanthocyanins.

The ray cells close to the cambium were lined with leucoanthocyanins (compare with the phenolic membrane substance of Erdtman[6] and the lining observed by Pew[7]). The contents of the sapwood ray cells were observed to be greater in amount at increasing distances from the cambium, assuming a clearer and brighter red colour. Only in the sapwood adjacent to the heartwood boundary did the vertical parenchyma also contain leucoanthocyanins. At the boundary and in the heartwood the fibres were red and in the case of *Eucalyptus camaldulensis* red inclusions were also observed. Those cells immediately surrounding kino veins in *Eucalyptus obliqua* were filled with leucoanthocyanins, but only small amounts were evident in the ray cells a short distance from the injury. These observations support the views of Bate-Smith and Metcalfe[8] that the materials in their wood sections reacting with iron are most commonly leucoanthocyanins (see also ref. 9) formed *in situ*.

A marked decrease in the amount of glycosides and increase in aglycones has recently been observed after the sapwoods of *Schinopsis*[2], *Prunus*[10] and *Eucalyptus* spp.[11] were changed to heartwoods. It is evident that physiological changes affect the nature of the chemical constituents. The above evidence indicates that the glycoside moieties (and probably other carbohydrates) are metabolized in the living cells of the sapwood, particularly in the region of increased activity at the heartwood boundary. Leucoanthocyanins appear to be a common product of this metabolism. Recently, it was found that the amount of (+)-catechin was much lower in the heartwood than in the sapwood of species which also contained leucoanthocyanins[2,10,12]. Consequently, it seems likely that the condensed tannins in many woody plants are formed by the polymerization of leucoanthocyanins, either alone or in conjunction with catechin and other compounds.

Electron Spin Resonance Investigations of Rat Liver and Rat Hepatoma

Studies concerning the role of free-radical reactions in biological processes have long been hampered by the lack of a method for detecting free radicals in biological systems. The recent investigations of Commoner[1] have shown that electron spin resonance techniques offer considerable promise for this purpose. This communication describes, first, an investigation of sample preparation and handling methods, and second, a qualitative comparison of electron spin resonance signal intensities from normal rat liver tissue with Novikoff rat hepatoma.

Measurements were carried out at 9,000 Mc./s. using a magnetic field of 3,200 gauss. The g values observed were almost identical with that of the free electron. The size of all samples was approximately 1·7 gm. The free radical contents were inferred from measurements reflecting the area under the absorption curve, which is proportional to the free radical content of the samples studied.

Table 1 shows that freeze-dried rat liver samples contain about five times as many free radicals per unit weight of living tissue as samples chilled to − 196° C. instantly upon excision of the liver and examined in the electron spin resonance spectrometer without allowing the sample temperature to exceed − 130° C. at any time. Since the electron spin resonance line width of freeze-dried samples was found to be less than that of the instant-frozen samples, it is possible that the free radicals created during the freeze-drying process are artefacts, completely different from those originally present in frozen, but otherwise unaltered, material. This conclusion is supported by the fact that Miyagawa and Gordy *et al.*[2] have found that the electron spin

Table 1. Free-Radical Content of Rat Liver and Hepatoma obtained from Electron Spin Resonance Measurements carried out at −130° C.

Sample type	No. of samples	Free-radical content in molecules × 10^9/gm. wet weight*
Freeze-dried rat liver	2	10
Immediately frozen rat liver	3	1·9
Rat liver stored at 0–25° C. from 22 hr. to 2 weeks	3	1·3
Immediately frozen rat hepatoma	3	0·67

* Values given are based on an estimate of the electron spin resonance spectrometer sensitivity obtained using a 6 × 10^{-5} gm. diphenylpicrylhydrazil sample for calibration.

resonance signal from lyophilized tissue arises from sorbed molecular oxygen.

Although storage of the unaltered samples at 0–25° C. causes a reduction in electron spin resonance signal strength compared with that observed for instantly frozen samples (Table 1), no significant difference in signal amplitude was found for storage periods ranging from twenty-two hours to two weeks. Therefore, the conclusion is that some of the free radicals initially present in the instantly frozen samples are unstable at room temperature; the remainder appear to be extremely stable.

Quite possibly part of the observed electron spin resonance signal (particularly that part which is stable at room temperature) observed in frozen liver tissue is caused by the presence of certain paramagnetic trace elements. From the careful investigations of Heggen and Strock[3] it is concluded that for those paramagnetic ions exhibiting a *g* value close to 2·00, only one or two trace elements occur in large enough concentrations to contribute to the signal. However, more work is being carried out at the present time to determine to what extent such ions are affecting the signal intensities.

Investigations of hepatoma tissue were carried out using Novikoff tumour transplant material originally induced by use of diacetylaminofluorene. As seen from Table 1, the free-radical content of instantly frozen rat hepatoma is only roughly one-third of that found in similarly processed normal liver.

Thus, the number of unpaired electrons observed in frozen samples is much lower than that obtained for freeze-dried specimens. The differences in signal strength between instantly frozen rat liver and rat hepatoma is much greater than that reported by Commoner[1], who used the freeze drying process.

We wish to acknowledge many helpful discussions of this material with William H. Storey, jun., and George Pish. Dr. Karl Paschkis, of Jefferson Medical College, kindly supplied the rats having tumours.

Detection of Polarization by Biological Organisms

For the construction of colour filters Christiansen[1] had the idea of using scattering to attenuate unwanted wave-lengths. He used a finely divided isotropic scatterer in an isotropic medium to achieve partial monochromatization. One of us (A. N. F.), in connexion with a Science Fair project on these filters, suggested the use as a scatterer of a bundle of parallel transparent birefringent fibres immersed in an isotropic medium the refractive index of which matched one of the refractive indices of the fibres. Light vibrating in a direction characterized by this index will then be transmitted unattenuated by scattering. A Patent Office search reveals a number of patents involving scattering to attenuate unwanted components[2]. However, there seems to be no recognition of this method of achieving polarized light in the scientific literature. These patents seem to have been largely overlooked.

There are a large number of papers devoted to the responses to polarized light of various biological organisms[3]. In most cases, the method used to determine the plane of polarization is not known.

We wish to suggest that the above-mentioned polarizing mechanism may well play the necessary part in such determination. Animal tissues often contain bundles of parallel transparent birefringent fibres immersed in a liquid or gel medium. If the index of refraction of the medium is other than the average of the two refractive indices of the fibres, then any transmitted light will be partially polarized. If it matches one of the refractive indices, then that component will be a maximum in intensity. We intend to search for such polarizers.

Stable Test-Papers for Seminal Acid Phosphatase

The acid phosphatase test has proved its usefulness in seminal stain examinations and is now in widespread use[1–4]. The desirability of preparing a stable form of the reagent was obvious, more especially for 'scene-of-crime' searching, post-mortem examinations and for scientists and clinicians without laboratory facilities.

We have prepared stable test papers as follows.

200 mgm. α-naphthyl phosphoric acid and 400 mgm. diazo-*o*-dianisidine (as 'Brentamine Fast Blue *B* Salt', Imperial Chemical Industries) are dissolved in 100 ml. *M*/5 citric acid/sodium citrate buffer of *p*H 4·9. Filter papers soaked in this solution are immediately blotted and left to dry singly at room temperature. These manipulations are best carried out in light of low intensity. The papers are

then stored in opaque bottles at room temperature over calcium chloride. In use the papers are wetted with distilled or tap water and pressed against the suspected seminal stain. A positive reaction is shown by an intense purplish colour.

Discoloration on storage proceeds only slowly and we have found the papers to be usable up to a year from manufacture, with a little activity remaining up to two years (storage temperature 15° C. ± 5° C.). Storage at 55° C. for some weeks is possible, showing that temperature will not be a limiting factor for use in tropical countries.

A modification of the test is to interpose wet filter paper between the stain and the test-paper instead of placing them in direct contact. This possesses the advantage of reducing contamination of the seminal stain by the reagent (this is especially important where serological tests are afterwards to be applied): it permits also the use of test papers which, although discoloured by long storage, are still usable. This is because extracts from the stain and test paper pass into the clean filter paper and react there. The insoluble coloured decomposition products remain on the test paper.

Detection of Hæmoglobin, Hæmoglobin–Haptoglobin Complexes and other Substances with Peroxidase Activity after Zone Electrophoresis

HÆMOGLOBIN and complexes of serum haptoglobins with hæmoglobin, have peroxidase-like activity which permits their detection in small amounts. For this purpose benzidine[1,2], *o*-tolidine[2], guaiacol[3] and leucomalachite green[4] have been employed. However, none of these substances has proved entirely satisfactory. The colours given by benzidine and tolidine fade within minutes[5], especially when applied to starch-gel strips, and both reagents give appreciable background staining on paper. Instability of benzidine and guaiacol colours used to detect horse-radish peroxidase after paper electrophoresis has been noted also by Jermyn and Thomas[6], who reported that *o*-anisidine, *p*-aminodimethylaniline and hydroquinone were even less satisfactory as reagents for the detection of peroxidases. Malachite green, formed from leucomalachite green, is more stable; but we have found the reagent much less sensitive than either benzidine or tolidine.

In studying the haptoglobins of human serum we have sought a more satisfactory peroxidase colour reaction and have compared a number of likely substances. The reagents in each case were prepared by dissolving 100 mgm. of the test substance in 70 ml. of ethanol and adding 10 ml. of 1·5 *M* acetate buffer (*p*H 4·7) and 18 ml. of water. Immediately before use 2 ml. of hydrogen peroxide (100 vol.) was added. The composition of the reagents was thus similar to the benzidine reagent used by Moretti *et al.*[1]. After electrophoresis, paper or starch-gel strips were placed in the reagent for 15 min. and were then washed in three changes of water.

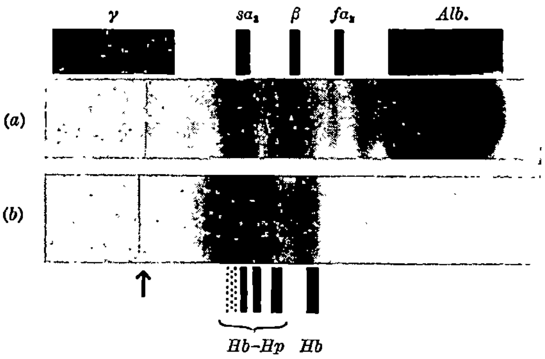

Fig. 1. Starch-gel electrophoretic strips (borate buffer, *p*H 8·6; ref. 7) of human serum containing added hæmoglobin. *a*, stained with naphthalene black to show proteins; *b*, stained with dianisidine reagent to show hæmoglobin–haptoglobin complexes and photographed after 2 weeks. *Hb*, hæmoglobin; *Hb–Hp*, hæmoglobin–haptoglobin complex. Arrow indicates point of insertion

Results are shown in Table 1 and indicate that *o*-dianisidine was the most satisfactory reagent. It gives an intense brown colour in zones having peroxidase activity. After washing and drying, the reactive areas on paper become brown-pink while the paper shows a very pale pink background. In starch-gel strips the coloured areas remain unaltered for at least a month while the background remains perfectly white. Fig. 1 illustrates a starch-gel electrophoresis strip of human serum containing added hæmoglobin.

Table 1. COMPARISON OF PEROXIDASE REAGENTS

Substance*	Sensitivity† (10^{-2} μgm./cm.^{2})	Comment
o-Dianisidine	5	Colour stable
o-Tolidine	10	Marked background colour fades in hours
Benzidine	20	Colour fades in minutes
p-Anisidine	40	Colour fades in minutes
Amidopyrine	>80	—
Leucomalachite green	>80	—
Guaiacol	>80	—

* All materials were obtained from British Drug Houses, Ltd.
† Minimal concentration of hæmoglobin detectable on paper.

While most of our experiments were carried out with hæmoglobin or with hæmoglobin–haptoglobin complexes, we have also found the dianisidine reagent satisfactory in the detection of peroxidase activity in extracts of horse-radish (*Cochlearia armoracia* L.) and other plants.

We should like to thank Miss Hania Ayzner for technical assistance in this investigation.

Increased Survival of Rats irradiated with X-Rays and treated with Parathyroid Extract

An increase in the survival of rats irradiated with X-rays has been found when parathyroid extract is given either before or after the irradiation.

In our experiments, each rat received 200 U.S.P. units (2 ml.) of parathyroid extract (Eli Lilly) subcutaneously in the dorsothoracic region; control animals received an equal volume of normal saline. Both the parathyroid extract and the saline contained phenol as a preservative and were injected under sterile conditions. Males of a laboratory strain of hooded rats were used. They weighed 275–350 gm. at the beginning of each experiment. In one series, injections were given 12–18 hr. before irradiation. In a second series, animals were injected immediately after irradiation. All animals received 760 r. whole-body irradiation (measured in air) with 2,000 kVp. X-rays (1·5 m.amp.). This dose was given 65 cm. from the target at 400 r./min. No filters were used. Food and water were given *ad libitum* during the post-irradiation period.

When parathyroid extract was injected before or after irradiation, a difference was observed between the percentage surviving in the control and treated animals. By 20 days, this difference became highly significant (Table 1).

Table 1. Effect of Parathyroid Extract on the Number of Rats surviving 760 r. Whole-body Irradiation with X-Rays

	Days after irradiation						Percentage surviving (30 days)
	0	10	15	20	25	30	
Pretreatment (12–18 hr. before irradiation)							
Saline (2 ml.)	119	117	94	74	68	63	52·9
Parathyroid extract (2 ml.)	119	118	109	102	98	97	81·5*
Post-treatment (immediately after irradiation)							
Saline (2 ml.)	56	50	23	14	12	12	21·4
Parathyroid extract (2 ml.)	54	51	41	38	37	36	66·7*

* $P < 0{\cdot}001$ (chi-square)

When parathyroid extract was injected before irradiation, survival at 30 days irradiation was 52·9 per cent in the controls and 81·5 per cent in the treated animals (Table 1). When injections were given after irradiation, survival was 21·4 per cent in the controls and 66·7 per cent in the treated rats. This represents an increase in survival of 28·6 per cent and 45·3 per cent for rats injected with parathyroid extract before and after irradiation, respectively. These differences were highly significant ($P < 0{\cdot}001$).

Between 30 and 60 days, the difference between the percentage surviving in the controls and treated animals was still evident, although slightly reduced. The percentage surviving in the controls was 51·3 and in the treated rats was 73·1, when treatment was administered before the irradiation. In rats injected after irradiation, the corresponding percentages at 60 days were 16·1 and 57·4.

It is not clear why fewer animals survived in the control group injected with saline immediately after irradiation (21·4 per cent) than in the controls injected before irradiation (52·9 per cent) (Table 1). However, a much greater proportion of gastro-intestinal hæmorrhage occurred in the animals which died in the series injected after irradiation. This may have been the cause of the difference.

We conclude that the parathyroid extract used protects against radiation death. Experiments are in progress to determine whether this effect is a result of the activity of the hormone (that is, its ability to increase serum calcium[1]) or to some other property of the extract.

Protective Action of Venoms containing Phosphatidase-*A* against Certain Bacterial Exotoxins

We reported recently that a fraction of venom of the Australian tiger snake (*Notechis scutatus scutatus*), rich in hæmolysin, protects mice against both the dermonecrotic and lethal action of staphylococcal alpha toxin. Such an effect is observed when this fraction of the venom is injected either together with the toxin or separately[1].

Further work has shown that protection is not afforded by the crude venom of the tiger snake, nor by a fraction of the venom rich in neurotoxin but poor in hæmolysin. On the other hand, we have observed that the crude venom of the Australian black snake (*Pseudechis porphyriacus*), of the king brown snake (*Pseudechis australis*), and of the honey bee (*Apis mellifera*) gives the same order of protection against the lethal action of staphylococcal toxin in mice as does the hæmolysin-rich fraction of the venom of the tiger snake. The former three venoms, like that of the tiger snake, are strongly hæmolytic, all containing the enzyme phosphatidase-*A* (Doery, H. M., unpublished work). Unlike the venom of the tiger snake, however, they are not powerfully neurotoxic.

By toxoiding the hæmolysin-rich fraction of the venom of the tiger snake with 0·2 per cent formalin, the ratio of the resultant toxicity to the protective power was reduced from that of the untoxoided material. A notable protection against the lethal action of staphylococcal toxin was obtained with this toxoided fraction when it was administered up to 30 min. after the staphylococcal toxin.

Further, we have observed that both this toxoided fraction of tiger-snake venom and non-toxoided crude bee venom protect mice against intraperitoneal challenge with living staphylococci, the virulence of which was enhanced by Boake's[2] method (Table 1). This finding supports evidence that death following the intraperitoneal injection of mice with such living challenge is due to the production of alpha toxin (North, E. A., unpublished work).

It is known that the products of the action of phosphatidase-*A* on lecithin are a fatty acid and lysolecithin. Further, it was shown many years ago that soaps of certain long-chain fatty acids neutralize a number of bacterial toxins *in vitro*[3].

We have confirmed these findings as regards staphylococcal alpha toxin, tetanus toxin and diphtheria toxin using either sodium oleate or sodium linoleate. We have failed to demonstrate protection with the soap of the corresponding saturated acid, sodium stearate. In addition, we have observed that

Table 1. PROTECTION OF MICE AGAINST INTRAPERITONEAL CHALLENGE WITH LIVING VIRULENT STAPHYLOCOCCI BY A TOXOIDED TIGER SNAKE VENOM FRACTION AND CRUDE BEE VENOM

Test	Protective agent	Treatment when given in relation to challenge	Route	Day of death	Survivors after 7 days
1	Nil (controls)	—	—	1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1	4/20
	0·02 mgm. toxoided tiger snake venom fraction	75 min. before	Subcutaneous	1 1 1 2 3 4 5	13/20
	,, ,, ,,	45 min. after	Intravenous	1 1 1 1 1 1 1 1 1 1 3 3 7	7/20
2	Nil (controls)	—	—	1 1 1 1 1 1 1 1 1 1 1 1 1 3	2/15
	0·02 mgm. toxoided tiger snake venom fraction	95 min. before	Subcutaneous	1 2 2 4 4 5 5	8/15
	1/40 of one bee sting	100 min. before	Subcutaneous	1 1 1 1 2 4 4 7	7/15

All mice were challenged intraperitoneally with 1 ml. of a suspension of living coagulase-producing *Staphylococci* the virulence of which was enhanced by Boake's (ref. 2) clotting mixture.

protection against the lethal action of staphylococcal toxin in mice may be afforded by sodium oleate administered separately. Evidence has also been obtained that the hæmolysin-rich fraction of the venom of the tiger snake is antagonistic to the action of tetanus toxin in mice.

These observations suggest a possible defence mechanism against *in vivo* action of certain bacterial toxins. Phosphatidase-*A*[4] and lysophosphatides[5,6] have been reported to exist in animal tissues as such. Long-chain fatty acids may be liberated from phosphatides in cell envelopes as a response to the action of these toxins. The nature of the suggested interaction between the bacterial toxins and the fatty acids is not understood. This work is being reported in detail elsewhere.

Comparison of the Effect of Ultra-violet and X-rays on the Capillaries of the Frog's Web

THE web between the toes of the frog is very suitable for the examination of the primary processes in the skin after irradiation with ultra-violet light, since the very thin corneal layer permits the entry of ultra-violet light of short wave-length. The transparency is measurable and makes possible the estimation of the absorption at different wave-lengths. To compare the effects of different wave-lengths, knowledge of the absorption coefficient at the site of biological action is necessary.

Transparency measurements were carried out in the range 280–600 mμ; below 280 mμ there was no transparency. The thickness of the layers (stratum corneum on each side, its layer of compensation, Malpighian layer and the dermis in the centre) was determined in histological cross-section. We were unable to detect a significant change in the absorption coefficient for the different layers, and therefore no influence of the histological structure was observed.

Fig. 1 shows average percentage of the applied radiation absorbed by a layer 1μ thick plotted against the depth of the layer. The diameter of the field measured was 2·4 mm. Ultra-violet irradiation was supplied by a high-pressure mercury lamp[1], *HBO* 2001. The radiant flux density was measured with a bolometer.

The reactions of the blood circulation to irradiation have been studied by Giersberg and Hanke[2] and by Bücker and Hanke[3]. Together with histological effects and changes in transparency with the changing water-content of the layers, the flow of blood was blocked even though the width of the vessels remained constant. The doses which produced this effect in 50 per cent of the animals were 10 watt sec. cm.$^{-2}$ (280 and 297 mμ) and 35 watt sec. cm.$^{-2}$ (313 mμ). 366 mμ had no effect. The absorption per layer 1μ thick was 0·3 per cent at 280 mμ (Fig. 1), 0·58 per cent at 297 mμ and 0·69 per cent at 313 mμ in the region of the capillaries on the irradiated side. The relative efficiency of the different wave-lengths

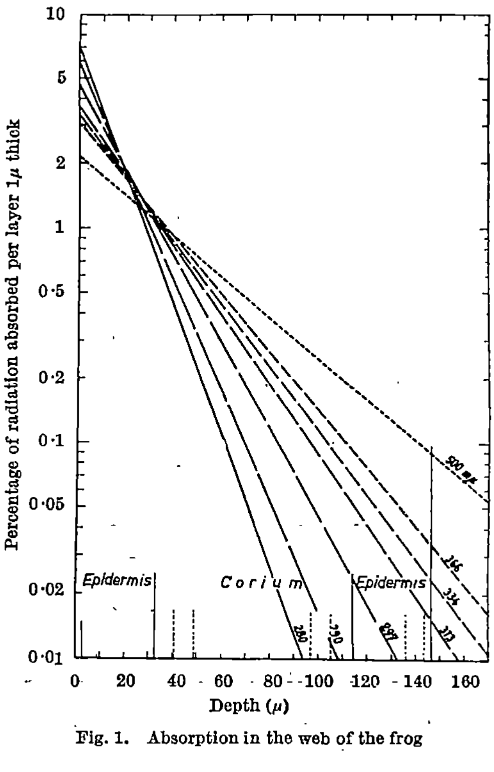

Fig. 1. Absorption in the web of the frog

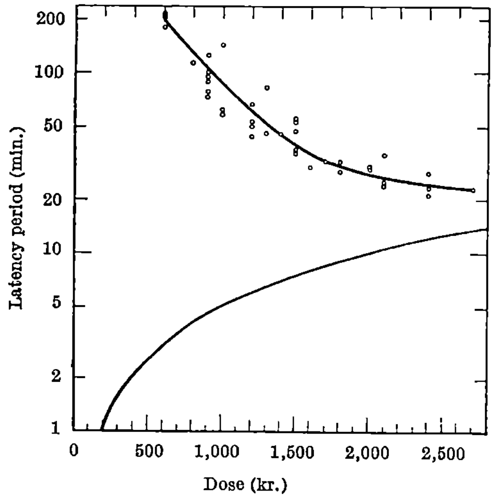

Fig. 2. Dependence of latency period on dose (upper curve). Dose-rate 200 kr./min. Curve below shows irradiation times

280, 297 and 313 mμ was 1 : 1·9 : 8. It is evident that the capillaries or their neighbourhood are the site of the primary effect.

After irradiation with X-rays ('Dermopan' apparatus, 45 kV., 25 m.amp., beryllium window, 35 mm. from tube axis, 200 kr./min.), blockage in the capillaries occurred only, after a latent period, within the limits of the irradiated field. The effect was caused by a dose of 600 kr. and more. The latent period decreases exponentially with the dose. The differences in Fig. 2 at high doses result from the longer irradiation times. The effect after X-irradiation with 1,750 kr. occurs 30 min. after the start of irradiation. Ultra-violet irradiation (297 mμ) requires a radiant flux-density of 55 mwatts cm.$^{-2}$ during 30 min. to produce stasis in 50 per cent of the animals. In these conditions the ultra-violet energy absorbed (297 mμ) at the site of its biological effect must be 35 times higher than the X-ray energy (the absorbed energy after irradiation with 1,750 kr. is 1·63 mwatt sec. cm.$^{-2}$ per layer 1μ thick; the energy absorbed in the capillary layer during 30 min. ultra-violet irradiation (297 mμ) is 58 mwatt sec. cm.$^{-2}$ per layer 1μ thick, radiant flux density 55 mwatt cm.$^{-2}$). The differences between the effects of ultra-violet light on animals are larger than those of X-rays. These differences depend on the thickness of the absorbing layers, on a yearly rhythm, and on the natural ultra-violet background. After X-irradiation the differences are small, and depend on internal factors such as blood-pressure, maintenance of blood in the capillary system, etc. The differences in the induction period are shown in Fig. 2. Histologically there are some differences between the effects of the two kinds of rays which we used[4].

Biochemical Basis of Disturbances caused by Thermal Stress in the Central Nervous System of Man

Investigations on men subjected to thermal stress showed characteristic changes in behaviour as well as disturbances in higher nervous activity. Thermal stress at first causes increased excitability of the central nervous system, the subjects showing an augmented mobility, a vivid interest in their environment and a marked loquacity. Later, this condition undergoes a change and the subjects fall into a state of drowsiness (without, however, any tendency to sleep) and apathy[1]. Measurements of the conditioned reflex-[2] and serial reaction-time[3] revealed changes of these values under the influence of environmental high temperature.

This investigation aimed at determining the biochemical events by which such disturbances in the functions of the central nervous system are caused. Two enzymes present in blood, namely, acetylcholinesterase (true cholinesterase) of erythrocytes and cholinesterase (pseudo-cholinesterase) of plasma were investigated. The first of these enzymes is identical, or almost identical, with the acetylcholinesterase present in the central nervous system[4]. Establishment of changes in the activity of this enzyme, so important in conduction and transmission processes, could serve as at least a partial interpretation of the disturbances caused by thermal stress.

The second enzyme investigated, pseudo-cholinesterase, is present in many tissues. Its presence, among others, in the autonomic ganglia indicates a connexion with the functions of the autonomic part of the nervous system. Its exact role therein, however, is unknown. The activity of pseudocholinesterase has been investigated for the present only to detect changes caused by thermal stress.

The investigations were carried out on 50 male subjects aged between 20 and 47 years. The subjects were medically examined and considered to be healthy. The subjects were placed, naked and

Table 1

Enzyme: Substrate:		Acetylcholinesterase of erythrocytes Acetyl-β-methylcholine		Cholinesterase of plasma Butyrylcholine	
Time of blood taking		Before stress	After stress	Before stress	After stress
b_{30} per 0·05 ml. of whole blood	No. of subjects	50	50	50	50
	No. of determinations	100	100	100	100
	Mean	76·1	77·2	29·9	30·6
	Standard error	± 2·3	± 2·3	± 0·7	± 0·7
	Standard deviation	± 16·5	± 16·2	± 5·1	± 5·1
	Range	52·1–137·1	51·0–132·9	10·0–42·1	13·5–44·0

The symbol b_{30} denotes cholinesterase activity. It indicates the amount of carbon dioxide (μl.) evolved during the period of 30 min. minus the amount of carbon dioxide evolved during the same period by spontaneous (non-enzymatic) hydrolysis of the substrates (four for acetyl-β-methylcholine and three for butyrylcholine) (see ref. 7).

stretched out on the wooden floor at complete rest for 2 hr., in a climate chamber which has been described by Dutkiewicz *et al.*[5]. The activity of both enzymes was estimated with the gasometric technique exactly as described by Augustinsson[6]. Acetyl-β-methylcholine chloride ('Amechol', Savory and Moore, Ltd.) was used as substrate for acetylcholinesterase, and butyrylcholine chloride (L. Light and Co., Ltd.) for cholinesterase.

The results are shown in Table 1.

There are no significant differences in the activity of the two enzymes investigated before and after 2 hr. in the climate chamber. The results obtained agree with those of Field *et al.*[7], who also found no changes in the activity of acetylcholinesterase of brain in rabbits with pyrexia.

Investigations of the acetylcholine content in the brain hemispheres of mice exposed to conditions of thermal stress similar to those described above for our human subjects showed no differences in values obtained for animals in normal and in heated atmospheres[8]. If, therefore, it is admissible to compare experimental results obtained for men with those obtained for mice, it appears probable that cholinergic neurones and synapses are not involved in the changes in behaviour and higher nervous activity caused by thermal stress.

We wish to thank Mrs. A. Lewicka for help in performing these experiments.

Effect of 8-Azaguanine on Antibody Synthesis *in vitro*

CREASER[1] has shown that 8-azaguanine is strongly inhibitory to induced enzyme formation in bacteria, but less so to the formation of 'constitutive' enzyme. On the basis of these findings and other evidence[1], Creaser suggested that induced enzyme formation might be mediated by unstable ribonucleic acid templates needing continuous resynthesis, while 'constitutive' enzyme formation might utilize more stable templates.

The concept has been advanced that antibody formation may be analogous to induced enzyme formation (for example, ref. 2). To gain information on this, the effect of inhibition of the incorporation of carbon-14-leucine into antibody protein and into a 'constitutive' spleen cell protein was studied. 8-Azaguanine was taken as an inhibitor particularly of nucleic acid synthesis and *p*-fluorophenylalanine as an inhibitor particularly of protein synthesis.

Spleen cell suspensions were prepared from rabbits three days after an anamnestic injection of egg albumin. The details of this preparation will be described elsewhere[3]. Since the rate of incorporation of carbon-14-leucine into antibody by the spleen cell preparation is linear for at least 24 hr.[3], this period was adopted for the measurement of antibody synthesis. At the end of the incorporation period, radioactive antibody was isolated by co-precipitation with added rabbit anti-egg albumin and egg albumin. Control precipitates, made with an unrelated antigen–antibody system (human γ-globulin–antihuman γ-globulin), yielded less than 4 per cent of the activity found in the test precipitates (egg albumin, anti-egg albumin) (Table 1). The fraction insoluble in trichloracetic acid prepared from the insoluble material recovered from disintegrated cells was used as a 'constitutive' spleen cell protein.

Table 1. THE 24-HR. INCORPORATION OF CARBON-14-LEUCINE INTO ANTIBODY

Radioactivity in medium, c.p.m. ^{14}C-DL-leucine	L-Leucine conc. (μgm./ml.)	No. of cells*	Control γ-globulin, anti-γ-globulin p.pt. Total/c.p.m.	Egg albumin, anti-egg albumin p.pt. Total/c.p.m.
$3 \cdot 9 \times 10^6$	91	6×10^7	310 208	17,400 16,600
$2 \cdot 0 \times 10^6$	59	4×10^7	530 585	14,600 15,300
$0 \cdot 8 \times 10^6$	39	4×10^7	86 89	7,000 7,700

Precipitates were washed twice with 0·85 per cent saline with 2 mgm./ml. carbon-12-DL-leucine.

* 2×10^7 cells approximately equivalent to 10 mgm. wet weight.

As is evident from Fig. 1, isotope incorporation into antibody was sharply inhibited by 8-azaguanine (solid circles). However, there was also a very considerable inhibition of incorporation into the insoluble cell protein fraction (open circles). Furthermore, the same effect was seen with *p*-fluorophenylalanine, which also inhibited incorporation into antibody (solid triangles) more than incorporation into the insoluble fraction (open triangles). *p*-Fluorophenylalanine may be regarded as a general antagonist of protein synthesis, independent in its action of any peculiar lability of a ribonucleic acid template. The differences noted in isotope incorporation into antibody and into cell protein, therefore, may better be attributed to relative rates of the respective protein syntheses rather than, particularly, to differences in turnover rates of ribonucleic acid templates. Consis-

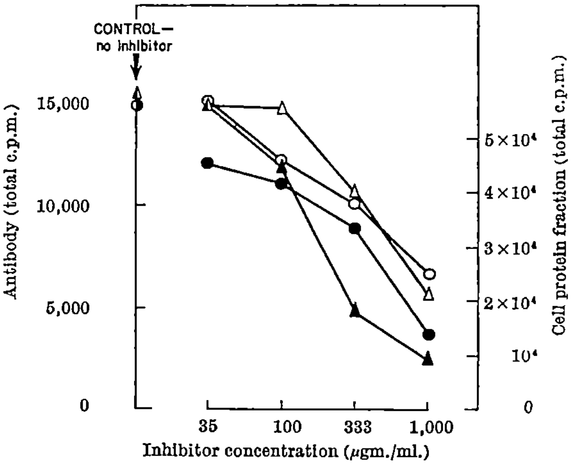

Fig. 1. Incorporation of carbon-14-leucine into antibody and insoluble cell protein fraction. Inhibition by 8-azaguanine and by *p*-fluorophenylalanine. ●—●, Antibody, 8-azaguanine; ▲—▲, antibody, *p*-fluorophenylalanine; ○—○, cell protein 8-azaguanine; △—△, cell protein *p*-fluorophenylalanine. Carbon-14-DL-leucine was added after 1 hr. of pre-incubation with inhibitors. Total counts/min. for antibody and cell protein refer to the totals produced per culture (20 mgm. wet weight)

Table 2. Inhibition of Phosphorus-32-Phosphate Uptake into Phosphate Fractions of the Cell by 8-Azaguanine and by *p*-Fluorophenylalanine

Inhibitor	Percentage of control uptake		
	Acid-soluble organic phosphate	Ribonucleic acid phosphate	Deoxyribonucleic acid phosphate
8-Azaguanine 300 µgm./ml.	70	72	53
p-Fluorophenylalanine 300 µgm./ml.	100	98	81

Cell suspensions were incubated for 1 hr. with phosphorus-32-phosphate after a 4-hr. period of pre-incubation with inhibitor.

tent with this interpretation is the finding (Table 2) that in a concentration (300 µgm. per ml.) at which 8-azaguanine has a 35 per cent inhibitory effect on antibody synthesis (cf. Fig. 1) there is a similar (30 per cent) reduction in phosphate turnover in the acid-soluble phosphate pool. Thus, though 8-azaguanine inhibits antibody formation, this is not an isolated event, but rather a manifestation of a general suppression of spleen cell function.

This tentative interpretation of the spleen cell system, however, is subject to several limitations. Amino-acid incorporation into antibody, made only in a small proportion of the cells, has been compared with amino-acid incorporation into a poorly characterized protein isolated from the whole cell population. Moreover, a considerable fraction of the latter appear to be dying[3]. Finally, in induced enzyme formation, it is the inhibition of the ability to begin making new protein which is measured, whereas, in the present system, it is the inhibition of the ability to continue to make new protein which has been measured.

Further experiments designed to approach these points are in progress. This work was supported by U.S. Public Health Services grant *E*1305.

Distribution of Choline Acetylase in Insect Conductive Tissue

It has been clearly shown that insects contain acetylcholine, cholinesterase and choline acetylase, and the work of Smallman[1-3] has done much to evaluate these. Since then, a more specific study of the substrate and enzymes in the conductive tissue of the American cockroach, *Periplaneta americana* L., has shown that acetylcholine occurs most abundantly in the brain and ganglionic tissue of the central nervous system[4], that the amount of acetylcholine increases after treatment with anticholinesterases when the nervous system shows intense electrical activity[5], and that acetylcholine is found in blood at this time[6]. These facts are compatible with those found for vertebrates.

Table 1. Synthesis of Acetylcholine by Choline Acetylase of Cockroach Conductive Tissue

Tissue	Rate of acetylcholine synthesis (mgm./gm./hr.)
Brain	50·6
Brain + sub-œsophageal ganglion	53·0
Ganglia of thoracic nerve cord	20·8
Sixth abdominal ganglion	18·0
Thoracic nerve cord	11·4
Ventral nerve cord	10·6
Abdominal nerve cord	6·2
Connectives of the thoracic nerve cord	2·6
Fifth leg nerve	2·0
Coxal muscle	0
Flight muscle	0

A further step in the evaluation of the role of acetylcholine has now been taken by determining the distribution of choline acetylase in conductive tissue of the cockroach. This work was carried out with homogenates of tissues, as more purified enzyme preparations required impractical amounts of tissue. The activity of choline acetylase of homogenates was determined by the amount of acetylcholine formed in incubates containing coenzyme *A*, acetyl phosphate, transacetylase, choline, salts and buffer (Mehrotra, K. N., and Chefurka, W., private communication). The rate of acetylcholine formation was linear for the incubation period of 15 min., and all work was carried out at 30° C., the experimentally determined temperature optimum for choline acetylase from both cockroach and housefly. This optimum is close to that found for insect eggs (Mehrotra, K. N., and Chefurka, W., private communication). Table 1 shows the rates of acetylcholine synthesis for nervous and muscle tissue. It is at once evident that the brain and thoracic ganglia contain the highest amount of choline acetylase. The results for the distribution of choline acetylase are striking, for they compare favourably with the distribution of acetylcholine[4] in the same tissues. Furthermore, the intracellular distribution of choline acetylase appears to be similar to that found for acetylcholine. At tissue weights equivalent to and in excess of that for nervous tissue, no synthesis was found in cockroach leg muscle. This observation is of interest for, as yet, no detectable amount of acetylcholine has been found in denervated cockroach muscle[7]. The synthesis-rate for cockroach brain is the highest yet reported for acetylcholine synthesis in either vertebrates or invertebrate conductive tissue.

The importance of the functional role of acetylcholine in insects must be considered in view of this evidence for the occurrence and distribution of acetylcholine and related enzymes in the nervous system of the cockroach, and the lack of evidence for physiologically significant amounts of other neurohormones. The details of this work and observations on the tissue distribution of cholinesterase will be published more fully elsewhere.

Metabolic Alteration in Leukæmia induced by a Virus

RECENT publications[1,2] reporting the induction of leukæmia in mice by cell-free extracts have re-awakened general interest in the role of viruses as oncogenic agents and, as a corollary, in the metabolic alterations induced by these agents. It has been shown in this laboratory that alterations in host cell metabolism induced by virus can be detected very soon after infection[3]. The current investigation was undertaken to see if analogous effects could be observed *in vivo* using one of the viruses inducing tumours. The agent investigated here was that described by Friend[2] as producing a leukæmia in mice, characterized by splenomegaly and an accumulation in the spleen of stem cells. The basic experiments were performed as follows: 150 mice were infected i.v. with 0·2 ml. of a cell-free filtrate from spleens of mice carrying the infection. 150 control mice received the same amount of cell-free filtrate prepared from normal spleen. Beginning the day after inoculation of the virus, and at the intervals thereafter indicated in Fig. 1, six infected and six control mice were selected at random and given intraperitoneal injection of 5 μc. of phosphorus-32. 3 hr. later the spleens of these animals were removed, weighed, dried in pre-weighed planchets, reweighed, the radioactivity determined, and expressed as c.p.m./mgm. dry tissue. The averaged wet-weights of the spleens from a typical experiment as well as the averaged c.p.m./mgm. dry spleen are given in Fig. 1. As part of the same experiment, on the fifth day some of the control and the infected mice received 300 r. of total body X-irradiation. The results for weight and radioactivity of the spleens of these mice examined on subsequent days are also included in Fig. 1.

It can be seen that even before spleen enlargement, the spleens in the infected animals took up more radioactive phosphorus than did those in the controls. This has been observed in four out of four experiments performed. Some variation occurred in the day-to-day uptake of phosphorus-32 by the spleens, but in the many (more than 40) observations made, the infected ones always had a higher radioactivity (as c.p.m./mgm.). The statistical significance was usually quite high; in the experiment reported here the P values for the differences between control and infected spleen uptakes was 0·005 or better. The administration of X-rays decreased the size of the infected spleens to normal, so that one could not have detected disease on the basis of spleen size alone. The uptake of phosphorus-32 was decreased in both the infected and control spleens. However, the differential between infected and their controls was as great as it was in the non-irradiated animals.

Table 1. EFFECT OF VARIOUS PATHOLOGICAL CONDITIONS ON UPTAKE OF PHOSPHORUS-32 BY SPLEENS

Condition	Average wet spleen weight		C.p.m./mgm. dry spleen weight		Percentage change
	Infected	Control	Infected	Control

Spontaneous AKr leukæmia	415	75	123	67	83
5. Gross virus-induced leukæmia	751	57	543	322	69

These animals were kindly supplied by: (1) Dr. Victor H. Haas; (2) Dr. Herbert Hasenclever; (3) Dr. Stephen O. Schwarts; (4) Dr. Lloyd Law; and (5) Dr. Ludwig Gross (ref. 1). At least six experimental and six control mice were used, and in most cases two or three such groups were used. Differences of less than 20 per cent are not considered significant.

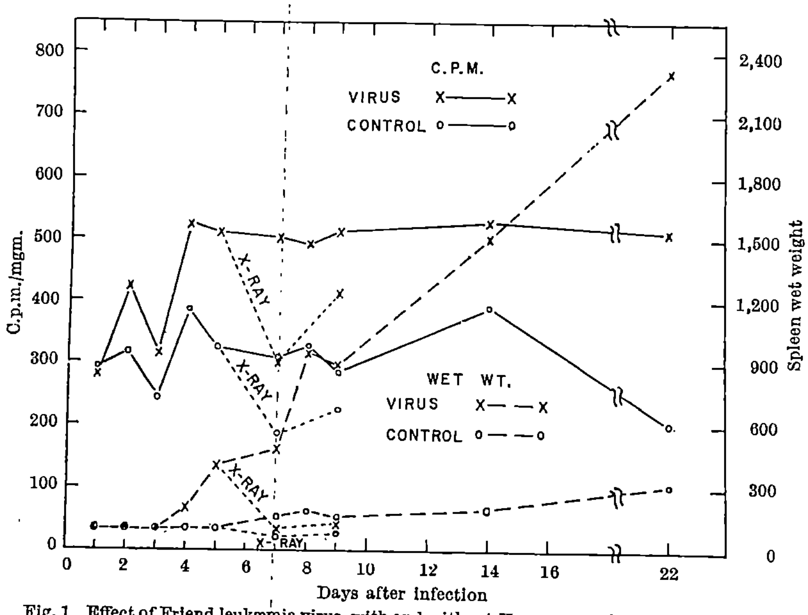

Fig. 1. Effect of Friend leukæmia virus, with and without X-rays, on uptake of phosphorus-32 by spleen

In other experiments 1 mgm. of cortisone was administered daily intramuscularly instead of X-rays. As with X-rays, the infected spleens returned to normal size, but their subsequent uptake of phosphorus-32 was accelerated over the controls as much as in those without cortisone.

In order to get some information about the specificity of the acceleration of phosphorus-32 uptake, several other diseases involving the spleen were studied in a comparable way. The disease and the uptake of phosphorus-32 by the spleens of these animals are given in Table 1. For reasons not relevant to these observations, the amount of radioactivity given was not the same for the different diseases. This accounts for the marked differences in absolute count from one disease to the next.

Table 1 demonstrates that the stimulated uptake of phosphorus-32 seen with the Friend agent is not a general phenomenen associated with spleen pathology or spleen enlargement, but is to some extent specific. It is striking that none of the transplanted leukæmias showed an increased phosphorus-32 uptake, while the spontaneous leukæmia and the other virus-induced leukæmia did. It should be recalled that some previous work with spleens of mice with transplanted leukæmia indicated that these tissues took up more phosphorus-32 than did normal controls[4]. The experimental procedures were quite different from those used here, and this may account for the differences in results.

With regard to sensitivity to X-rays and cortisone, the Friend leukæmia is like some chronic human leukæmias and lymphomas, whereas the transplanted mouse leukæmias in general are not[5]. With respect to phosphorus-32 uptake, as observed by us, the Friend leukæmia and the Gross virus-induced leukæmia resemble spontaneous mouse leukæmia and are different from the transplanted leukæmias we studied. It might be that the Friend leukæmia would be a valuable disease to use in screening programmes for drugs active against human leukæmia.

We are indebted to LeRoy Snellbaker and William Lane for technical assistance.

Use of Glucose labelled with Carbon-14 to determine the Amino-Acids Essential for an Insect

A chemically defined diet is required for determining essential dietary components by the classical deletion procedure. It has proved difficult to rear plant-feeding insects on artificial diets[1,2]. A method that would permit the determination of essential factors such as amino-acids for insects not reared on chemically defined diets would be useful. In 1952, Steele[3] showed that carbon-14 appeared in the non-essential but not in the essential amino-acids when uniformly labelled sucrose-^{14}C was ingested by a mouse. This finding provides the basis for an indirect method of determining which amino-acids are essential in the diet. The present report compares results of the indirect method with those of the classical deletion procedure[4] for the blowfly *Phormia regina* Meig.

Third-instar larvæ of the blowfly from a laboratory stock colony were injected with 3–6 µl. of a solution of uniformly labelled glucose-^{14}C containing 5,000 counts/min./µl.

The larvæ were maintained on fresh liver in test-tubes placed in a desiccator equipped to permit collections of carbon dioxide in absorption flasks containing suitable solutions of potassium hydroxide and barium chloride. After 24 hr. the carbon dioxide was found to be radioactive. This showed that glucose-^{14}C, when injected into the larvæ, was metabolized during this stage of development.

After 68 hr., 24 insects were recovered from 50 injected larvæ, 13 had pupated, 6 were in the prepupal form, and 5 were still feeding. The insects were homogenized in a Potter–Elvehjem homogenizer first with hot 80 per cent ethanol and then with boiling water. The resulting residue was hydrolysed with 6 *M* hydrochloric acid for 24 hr. and the acid was removed *in vacuo*. The combined extracts were evaporated to dryness. Finally, the dry matters from the extracts and hydrolysate were extracted with water; the solutions were combined and placed on a column of 'Dowex-50' in the H-ion form. The amino-acids were fractionated on the column by first washing with water and then by gradient elution with hydrochloric acid to a final concentration of about 6 *M*[5]. The fractions containing a particular amino-acid, as indicated by paper chromatography and published elution curves[5], were combined, evaporated *in vacuo*, and further purified by band paper chromatography. After development of a band chromatogram the amino-acid was eluted with water, the eluate was concentrated, and chromatographed further. Four solvent systems were used in all cases: *n*-butanol/acetic acid/water (4 : 1 : 5); ethanol/ammonia (95 : 5); water-saturated phenol; and 95 per cent ethanol; further purification of individual amino-acids was made in other solvent systems when necessary.

Amino-acids eluted from final paper strips were dissolved in water and determined quantitatively by a general colorimetric method[6], or by more specific tests for proline[7], phenylalanine[8], arginine[9], histidine and tyrosine[10]. An aliquot of the amino-acid solution containing about 1 µ*M* of the compound was plated on a copper planchet and the radioactivity was determined with a gas-flow counter.

Table 1 shows that serine, glycine, glutamic acid, and aspartic acid, found non-essential by the deletion procedure, all contained the largest quantity of radioactivity. Leucine, threonine, valine, histidine, *iso*leucine, lysine, phenylalanine, and arginine, shown to be essential by the classical method, contained little if any radioactivity. Thus, these twelve amino-acids may be grouped as essential or non-essential according to their labels of radioactivity.

The presence of intermediate quantities of radioactivity in proline and alanine indicates that both were synthesized from glucose. Both would be considered non-essential by the present method, whereas proline was classed as essential by the deletion procedure. This discrepancy is being investigated.

The carbon of glucose was not involved in the synthesis of tyrosine by larvæ of the blowfly. This indicates that tyrosine is essential, but the deletion

Table 1. SPECIFIC ACTIVITIES OF CARBON FROM AMINO-ACIDS ISOLATED FROM THE BLOWFLY *P. regina* AFTER INJECTION WITH UNIFORMLY LABELLED GLUCOSE-^{14}C, AND AMINO-ACID REQUIREMENTS AS DETERMINED BY THE DELETION PROCEDURE

Amino-acid	Specific activity (c.p.m./µ*M* carbon)	Reported requirement (ref. 4)
Serine	22·6	–
Glycine	17·3	–
Glutamic acid	15·1	–
Aspartic acid	14·0	–
Proline	7·9	+
Alanine	3·5	–
Methionine	0·9	–
Leucine	0·6	+
Threonine	0·5	+
Cystine	0·3	–
Valine	0·3	+
Histidine	0·3	+
*iso*Leucine	0·3	+
Lysine	0·2	+
Tyrosine	0·1	–
Phenylalanine	0·0	+
Arginine	0·0	+

method showed that it was non-essential. The essential amino-acid phenylalanine is the principal precursor of tyrosine in the mouse[3] and the silkworm[11]. If this condition exists in the blowfly, then no radioactivity would be expected in tyrosine.

When the amino-acids were individually deleted from a defined diet neither methionine nor cystine appeared to be essential[4]. However, afterwards it was shown by the deletion of two or more amino-acids that *P. regina* required either methionine or cystine in the diet[12]. The low levels of radioactivity in the methionine and cystine isolated from the glucose-injected larvæ agree with the latter results.

The radioactivity method described here gave results for the blowfly *P. regina* that were sufficiently comparable to those of the classical deletion procedure to warrant application to insects that cannot yet be reared on chemically defined diets. There are some discrepancies between the two methods which will need further study. This technique, when applied to the different stages of insects, should provide a means for comparing synthetic abilities during development. Furthermore, the possibility of introducing labelled substrates into insects by other means, such as feeding and vacuum infiltration, will permit the method to be extended. A more complete description of this work along with similar studies using uniformly labelled glutamic acid will be published elsewhere.

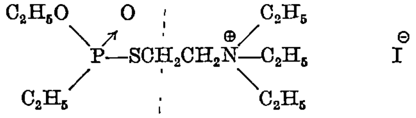
Role of Cholinesterase in Insecticidal Action

AMONG chemicals allied to the acaricide O,O′-diethyl-S-2-diethylaminoethyl phosphorothiolate, we examined the action of ethoxy ethylphosphinylthioethyl triethylammonium iodide (I) on the enzymes of the thoracic nerve cord of *Locusta migratoria migratorioides* R and F.



(I)

This substance, first prepared by Dr. R. Ghosh of this research station, is a moderate acaricide, being about half as toxic as parathion as a contact spray to *Tetranychus telarius* L. Against the locust it is of low toxicity, the *LD*50 being about 300–500 mgm./kgm. by injection. It is, however, a powerful *in vitro* inhibitor of the cholinesterase of the locust ganglion.

Metcalf *et al.*[1] have suggested that the lack of effect obtained by injection of cholinesters and prostigmine into insects[2,3] can be explained by the highly polar quaternary ammonium compounds being unable to penetrate the insect lipoid nerve sheath or synapses. On the other hand, the very closeness of the structure of this compound to acetylcholine suggests that it might well be broken down by enzymes occurring elsewhere than in the ganglion. Finally, the lack of correlation between toxicity to the locust and anticholinesterase activity of certain other non-polar organophosphorus esters[4] throws doubt on the importance of cholinesterase inhibition.

80–100 young virgin adult locusts were injected with 360–720 mgm./kgm. of (I) in buffered saline. Controls were injected with saline only. At intervals, the thoracic ganglia were dissected from a number of the injected locusts as follows: (1) 'Affected', prostrate, incapable of co-ordinated movement, no response to tarsal reflex, but not dead. (2) 'Unaffected', full co-ordination of movement and normal response to reflexes, indicating no interference with synaptic transmission, though, in the early stages, sometimes a little lethargic.

The dissected ganglia from affected, unaffected and controls were washed six times in ice-cold water, then ground in physiological saline (0·02 ml. per ganglion, ~ 0·02 ml./mgm.), diluted with 0·25 *M* sodium bicarbonate in physiological saline to give a concentration of 2 (in some cases 3) ganglia per Warburg flask. Cholinesterase activity was estimated by the usual Warburg method, involving the development of carbon dioxide from sodium bicarbonate with 0·002 *M* acetylcholine chloride as substrate. Activity measurements were taken over 1 hr. at 37° C.

With an inhibitor as powerful as (I) it is impossible to be certain of even the most meticulous washing method. A minute amount of the chemical left outside the ganglion would be intimately mixed with the enzyme during grinding and an inhibition be obtained *in vitro* which had, in fact, not occurred before dissection. To measure the amount of 'free' inhibitor, an equal amount of ground-up control ganglion homogenate was added to half the 'affected' and 'unaffected' flasks. If any unchanged (I) was present, it would exert its inhibitory power on the control homogenate as well as on the treated. On the other hand, if no free (I) was present, the activity of the mixture should be equal to that of a preparation containing an enzyme as active as the sum of the activities of the two constituent parts. This could be ascertained by the construction of standard curves, and in Table 2 'per cent inhibition' in the case of the mixtures refers to the expected values from these curves.

The validity of the method depends on knowing to what extent doubling the concentration of the enzyme affects inhibition at any one level. To establish this, a number of untreated locusts were dissected, and the

Table 1. PERCENTAGE *in vitro* INHIBITION FOR INCREASING ENZYME AND CONSTANT INHIBITOR CONCENTRATIONS

Concentration of inhibitor (*M*)	Ganglion equivalent in 2 ml.						
	2	3	4	5	6	7	8
1×10^{-9}	89	87	88	91	88	86	87
1×10^{-10}	82	81	79	71	62	65	59
1×10^{-11}	68		37		34		

Table 2. Course of *in vivo* Cholinesterase Inhibition

Experiment C55/34	Hours after injection							
	4		9		13		29	
	Acetylcholine decomposed (μmoles)	Inhibition (per cent)	Acetylcholine decomposed (μmoles)	Inhibition (per cent)	Acetylcholine decomposed (μmoles)	Inhibition (per cent)	Acetylcholine decomposed (μmoles)	Inhibition (per cent)
Affected	0	100	0	100	0	100	0	100
Affected + control	0	100	0·089	93	0	100	0·805	38
Unaffected	0	100	0	100	1·432	18	1·030	21
Unaffected + control	0·134	91	1·300	0	3·310	0	2·820	0
Control	1·478	—	1·255	—	1·748	—	1·300	—
Double control	3·850	—	3·810	—	3·265	—	4·080	—

ganglia homogenized in the usual way. Amounts of homogenate equivalent to 2–8 ganglia were then added to Warburg flasks containing a constant amount of inhibitor.

It appears that if the quantity of (I) is sufficient to inhibit the equivalent of 2 ganglia by about 90 per cent, quadrupling the amount of enzyme produces no significant change. Hence, if the ganglia of treated locusts show complete inhibition, and this was merely an *in vitro* effect produced subsequent to grinding, the addition of an equal amount of homogenate from untreated locusts should still give substantially complete inhibition of the mixture.

Other preliminary experiments have shown that when such an enzyme preparation is added to a solution of (I), the same amount of inhibition is obtained whether all the enzyme is added at once, or in two halves separated by 3 min. on ice. Finally, the slope of the *in vitro* inhibitor concentration/activity curve is such that the experimental dilution cannot affect the general picture. The above procedure would therefore appear to be reasonable.

Table 2 shows the result of a typical experiment. The dose injected was 360 mgm./kgm. and each figure is based on duplicate flasks.

The results of six experiments vary in detail, particularly on a time basis, but show essentially the same picture. While the inhibitor has great difficulty in penetrating the ganglionic sheath, some of it does reach the site of the enzyme and reacts with it. At the time of the first dissection there is an excess of the inhibitor present, resulting in inhibition of the mixtures as well as the affected and unaffected by themselves. At the time of the second dissection there is no further (I) left in the unaffected, the mixture of control and unaffected being as active as expected from the sum of control and unaffected. But all cholinesterase of the unaffected in this experiment and all or nearly all in other experiments appears to be inhibited, the enzyme showing no activity. After that, recovery takes place slowly. Even in the affected ganglia, detoxication seems to occur, as the mixtures in the later stages show some activity.

There is at least one other distinct enzyme, a phenylesterase, present in locust ganglia. (I) is a poor inhibitor of this, and in experiments of the type described its inhibition seems to be more correlated to toxic symptoms than that of cholinesterase. In the absence of information on its natural substrate or on the occurrence of other enzymes it is not possible to speculate on its role in the mode of action of phosphoric insecticides.

Unless synaptic transmission in the locust can be carried on normally by amounts of cholinesterase too small to detect by our method, it appears that a locust may have substantially all its ganglionic cholinesterase inhibited while showing no interference with normal nerve functioning. In that case it is hard to see what the role of this enzyme might be in the locust, or how its inhibition can be the cause of insecticidal action.

O'Brien[5] has shown that cockroaches poisoned by malathion show little *in vivo* reduction of cholinesterase activity, and similar results have been obtained by van Asperen[6] using O,O-dimethyl-O-2,2-dichlorovinyl phosphate on flies. Apparently there are cases when a toxic phosphorus ester produces little *in vivo* cholinesterase inhibition while killing, while others inhibit the enzyme very efficiently without killing.

It is hoped to publish a fuller account of experiments with this and other substances on more than one species in due course.

Pigmentation and Sexuality in Plants

Many angiosperms depend on insects or birds to accomplish pollination or seed dispersal, and the appropriate parts of the plants are brightly coloured, usually with carotenoid or flavonoid pigments. It is generally agreed that these pigments serve a useful purpose in attracting animal visitors, and therefore their presence has selective value; but while this may explain their production and maintenance in some angiosperms, it does not account for their original establishment in the plant kingdom. For carotenoids similar to those commonly found in flowers and fruits occur in all lower groups of plants, and anthocyanins (flavonoids) are found both in mosses[1] and in ferns[2]. Hence there is reason for believing that both types of pigment were produced in plants long before angiosperms had evolved, and have some function or functions unconnected with attracting the attention of animals.

No attempt will be made here to give a comprehensive survey of the alternative functions which have been suggested; this communication is concerned only with the suggestion that there is a connexion between these pigments and the biochemistry of sex. There is considerable evidence for such a connexion with carotenoids, which occur regularly in all groups of plants. The evidence includes the differential accumulation of carotenoids in the sex organs of fungi[3], and of algae[4], and a correlation between carotenoid concentration and the reproductive cycle in flowering plants[5]. In addition, Moewus[6] claims to have demonstrated an elaborate system of hormones regulating the sexual process in the alga *Chlamydomonas eugametos*, in which carotenoids and their derivatives play an important part, but attempts to reproduce many of Moewus's results have been unsuccessful[7] and his claims should be treated with caution.

A connexion between sexuality and the flavonoid pigments, which occur only sporadically in the plant kingdom, is much less probable. Moewus[6] states that the anthocyanin peonin and the anthoxanthin *iso*rhamnetin are sex-determining hormones in *C. eugametos*; but this is unconfirmed and subject to the same criticism as above. Another piece of evidence comes from the observations of Gascoigne, Ritchie and White[8] on flower pigments in *Casuarina*. These authors identified the anthocyanidins from seven species of the genus, three of which showed no difference between male and female flowers in this respect. In each of the other four species, however, flowers of one sex yielded an anthocyanidin not present in flowers of the other, as shown in Table 1. Of these species, *C. glauca* is always diœcious, *C. nana* is usually diœcious, and *C. rigida* and *C. suberosa* may be either monœcious or diœcious.

Table 1. ANTHOCYANIDINS FROM FLOWERS OF *Casuarina* SPECIES (From Gascoigne, Ritchie and White, ref. 8)

Species	Anthocyanidins represented in:	
	Male flowers	Female flowers
C. glauca Sieb.	cyanidin	cyanidin + delphinidin
C. nana Sieb.	cyanidin	cyanidin + delphinidin
C. rigida Miq.	cyanidin	cyanidin + delphinidin
C. suberosa Ott. et Dietr.	cyanidin + peonidin	cyanidin

There is clearly no consistent difference of pigmentation between the sexes in the genus as a whole, and so it seems unlikely that the anthocyanins play a fundamental part in the biochemistry of sexual differentiation. Nevertheless, the differences observed in individual species seem to be more than coincidental. In particular, *C. glauca*, *C. nana*, and *C. rigida* all show the same difference between flowers of opposite sex, although *C. glauca* is not closely related to the other two species. It is possible that the difference in pigmentation represents a sex-limited character, that is, having only a secondary connexion with sex. For example, flowers of both sexes may have an enzyme which, under suitable conditions, can catalyse the conversion of cyanidin to delphinidin, but which can function only in the biochemical environment of female flowers.

A study of anthocyanin pigments in the flowers of other diœcious plants has been made on a small scale to see whether the sex difference in *Casuarina* has a parallel elsewhere. Flowers or inflorescences containing anthocyanins were collected from the six species listed in Table 2. Extracts of anthocyanins were made from male and female flowers separately and analysed by paper chromatography, both with and without previous hydrolysis, using techniques and solvents recommended by Bate-Smith[9,10]. For each of the six species, flowers from several male and several female plants in the same population were analysed in this way. In no case was there any evidence of a qualitative difference in anthocyanin pigmentation between flowers of opposite sex. The anthocyanidins were tentatively identified, and are given in Table 2.

Table 2. ANTHOCYANIDINS FROM MALE AND FEMALE FLOWERS OF DIŒCIOUS PLANTS

Species	Anthocyanidins
Melandrium rubrum	cyanidin
Myrica gale	cyanidin + delphinidin
Petasites hybridus	cyanidin
Rumex acetosella	cyanidin
Salix repens	cyanidin
Urtica dioica	pelargonidin

This negative finding strengthens the view that anthocyanins have no direct connexion with sexual differentiation, and that the differences reported for species of *Casuarina* are not representative of some more general phenomenon.

I am grateful to Mr. L. A. S. Johnson, of the National Herbarium of New South Wales, for information about *Casuarina*.

Antibody Production by Single Cells

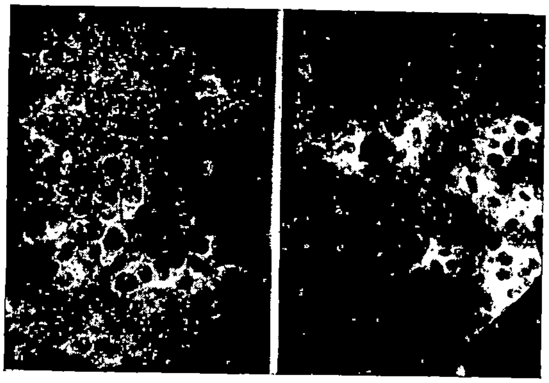
Nossal and Lederberg[1] described an ingenious and elegant method for showing that single cells from rat-lymph nodes, simultaneously stimulated with two antigens, formed antibody to one or other antigen but never to both.

This problem has been explored here by two further techniques which lead to the same general result as that given above, with different antigens and in a different animal species. The two methods employed the fluorescent antibody technique[2].

The first method used frozen sections of lymph nodes of rabbits simultaneously stimulated with two antigens (say *A* and *B*). The mature and immature plasma cells which contain anti-*A* were revealed by the 'sandwich' technique of Coons, Leduc and Connolly[3] using a dilute solution of a mixture of *A* and *B* and anti-*A* labelled with fluorescein. The distribution of fluorescent cells was photographed. The specific fluorescence of these cells was then quenched by exposure of the same microscopical field to long-wave ultra-violet radiation for 20–30 min. After this treatment a photograph confirmed the absence of specific fluorescence. Finally, after removal of the cover glass of the slide preparation, the cells containing anti-*B* were revealed by treatment of the section with fluorescein-labelled anti-*B*.

The second method used antibodies conjugated with red or green fluorochromes: sulphonyl chloride of rhodamine[4] or fluorescein *iso*cyanate. Frozen sections were treated with a dilute mixture of *A* and *B*, and then successively with anti-*A* labelled with fluorescein and anti-*B* labelled with rhodamine.

The first method has been applied to spleen sections from rabbits hyperimmunized by repeated intravenous injections of *Streptococcus pneumoniae* (type III) and crystalline hen's ovalbumin (tissue kindly supplied by Dr. J. H. Humphrey of the National



(a) (b)

Fig. 1. (a) Fluorescence micrograph. Medulla of rabbit spleen. Light areas (yellow-green fluorescence of fluorescein) indicate sites of antibody to capsular polysaccharide of *Str. pneumoniae* type III. Groups of antibody-containing cells (× 360). (b) Fluorescence micrograph. Same field as above, after quenching of specific fluorescence and after treatment to reveal distribution of anti-ovalbumin. Another set of cells distinct from those of (a) is revealed (× 360)

Institute for Medical Research) and to sections of popliteal lymph nodes of rabbits which were killed 3–6 days after a secondary stimulus of 50 *Lf* of diphtheria toxoid and 1 mgm. of ovalbumin adsorbed to aluminium phosphate, injected into a footpad. The animals had received simultaneous primary stimuli via the footpad with the same two antigens one month previously. The second method used the latter material only.

These treatments produced a heavy proliferation of plasma cells and their precursors in the pulp of the spleen or in the medulla of the popliteal node respectively. Comparison of the successive photographs provided by the first method, employing both combinations of antigens, showed that the two antibodies were located within distinct systems of plasma cell elements (Fig. 1, *a* and *b*). The use of the second method also resulted in two distinct sets of cells containing antibody, one with a yellow-green cellular fluorescence (of nuclei and cytoplasm) denoting anti-ovalbumin and one with the orange-red fluorescence denoting diphtheria antitoxin.

The use of the red and green fluorochromes would reasonably be expected to allow detection of two antibodies within a single cell providing that the amount of one is not grossly disproportionate to the other. The absence of such a result on a limited range of material does not prove that it cannot occur but implies at least that it is unusual.

On the basis of current hypotheses of clonal individuation in antibody formation[6,7] it might be expected that two groups of cells, which are derived by repeated divisions from widely dispersed precursors, would show a characteristic grouping. But although it was possible to discern a tendency for some cells of the same colour to occur in small clumps, marshalled clones of red and green were not apparent. This finding does not necessarily conflict with the hypothesis, providing the cells containing antibody are sufficiently motile in the medulla of spleen and lymph nodes. Evidence exists at least that they are motile[5]. Another type of lymphoid cellular proliferation which follows antigenic stimuli and which satisfies more fully the morphological requisites of clonal division is seen in the germinal centres of the lymphoid nodules. In certain circumstances these cells can be shown to contain antibody[8,9], and in my experience with animals producing both diphtheria antitoxin and anti-ovalbumin the cells of such a centre are nearly all of one kind (that is, either all green or all red by the above technique) and, thus far, appear to conform to the requirements of a clonal hypothesis.

Effect of Calcium Ions on the Binding of Chromium-51 to Erythrocytes *in vitro*

SINCE Gray and Sterling[1] introduced the method of labelling erythrocytes with chromium-51 *in vitro*, numerous papers have appeared showing the usefulness of this method for determining the total red corpuscle mass and the life-span of the individual's own erythrocytes[2].

In spite of the widespread use of chromium-51 as a labelling agent for the erythrocytes, relatively little is known about the basic mechanism of chromate binding to the erythrocytes. It has been shown repeatedly that the percentage uptake of chromium-51 by red corpuscles is higher using isotonic sodium citrate (ACD) solution as an anticoagulant than when heparin is used[3].

We wish to report that the presence of calcium ions in the incubation medium diminishes the uptake of chromium-51, added as sodium chromate, by erythrocytes and hæmoglobin *in vitro*.

Fresh human blood was drawn into different anticoagulants. The preparation of globin and hæmoglobin solutions will be described elsewhere by one of us (B. Z.). Labelled sodium chromate ($Na_2{}^{51}CrO_4$) with a specific activity of 5 μc./μgm. of metallic chromium was employed. 0·3 μc. of chromium-51 was added to 5 ml. of whole blood. The blood was incubated at 20° C. for 2 hr. After centrifuging, the red corpuscles were washed four times with physiological saline and, after hæmolysis, their radioactivity was compared to that of a standard sample.

Using heparin as an anticoagulant, the uptake of chromium-51 by the erythrocytes is reduced to two-thirds of the uptake in isotonic sodium citrate or oxalate solutions.

Table 1 shows that the calcium ions reduce the amount of chromium-51 taken up by erythrocytes suspended in saline or in recalcified sodium citrate plasma from about 90 per cent to about 60 per cent of the added chromate. The binding of chromium-51 to human globin or hæmoglobin *in vitro* is similarly decreased in the presence of calcium ions (unpublished work by B. Z.). This fact suggests that the effect of calcium ions on the uptake of chromate by red corpuscles is probably not due to a change in membrane permeability of the erythrocytes. Further

Table 1. THE EFFECT OF CALCIUM IONS ON THE UPTAKE OF CHROMIUM-51 BY HUMAN ERYTHROCYTES *in vitro*

Incubation medium	Percentage of uptake
ACD-solution* whole blood = 1/4	90

Volume and Acidity of Urine of Sheep fed Hay Rich in Silica and Effect of Dietary Salt Additions

THE results reported in this communication were obtained as part of a study related to a condition of silica urolithiasis which had been observed in steers on the Western Ranges[1] of Canada and the United States. Experiments in this laboratory have shown that sheep fed a hay from Western Canada containing 8·28 per cent silica (expressed on air-dry basis) excreted urine with a *p*H of approximately 5·5. Sheep in the control group that were fed a hay from Eastern Canada containing 0·78 per cent silica excreted urine with a *p*H of approximately 8·2. Consumption of water and excretion of urine by sheep fed the high-silica hay were about one-half that of the sheep in the control group.

The polymerization of silicic acid in aqueous systems is dependent on concentration and *p*H. Rate of polymerization is stated to be inversely proportional to the square of the silica concentration[2] and most rapid at *p*H 5·5–6 (ref. 3), 5·8 (ref. 4), 5–7 (ref. 5). It is therefore possible that the effects on volume and *p*H of urine that resulted from the feeding of Western grass hay may play a part in the formation of silica calculi.

The proximate composition and cation content of the two hays is given in Tables 1 and 2. The Western hay was mainly *Stipa*, probably *Stipa comata*, whereas that from Eastern Canada consisted of second cut red clover (*Trifolium pratense*). In the experiment reported here two groups of three sheep were used. One group was fed the Eastern and the other the Western hay, with salts added in order to render the cation content of the two diets approximately equal. Each sheep on Western hay received daily the following additions based on an average daily hay consumption of 1,000 gm. : sodium hydrogen phosphate, 2·4 gm. ; magnesium carbonate, 3·3 gm. ; magnesium sulphate, 4·7 gm. ; calcium carbonate, 15·0 gm. ; potassium bicarbonate, 15·6 gm. ; potassium chloride, 6·5 gm. Sheep fed the Eastern hay were given a daily addition of 112·5 gm. silica in the form of a commercial silica gel based on an average daily consumption of hay of 1,500 gm. Four samples of urine were collected daily over a 4-week period and the *p*H values determined on the fresh urine. 24-hr. urine volumes were determined three times a week.

Table 1. PROXIMATE PERCENTAGE ANALYSES OF EASTERN AND WESTERN HAYS

	Protein N × 6·25	Fat	Crude fibre	Ash	N-free extract
Eastern hay	11·74	1·46	31·32	6·72	48·76
Western hay	5·87	1·89	32·63	13·06	46·55

Table 2. MINERAL ANALYSES OF EASTERN AND WESTERN HAYS

	Na	K	Ca	Mg	P	SiO_2
Eastern hay	0·06	1·35	0·92	0·27	0·15	0·78
Western hay	0·02	0·44	0·32	0·08	0·12	8·28

Addition of silica to the diet had very little effect on either the volume or the *p*H of the urine. On the other hand, addition of salts to the diet of sheep fed the Western hay resulted in a urine volume comparable to that of the control group. In addition there was some elevation in urine *p*H but this was subject to considerable fluctuation. In order to overcome this fluctuation in *p*H, equivalent amounts of magnesium and potassium as magnesium carbonate and potassium bicarbonate were used to replace the magnesium sulphate and potassium chloride. This resulted in *p*H values of approximately 8·0. No ill effects attributable to the administration of salt were observed during the experiment.

Our studies on urolithiasis so far have suggested that low *p*H and low excretion of urine may be important factors contributing to the formation of silica calculi. If this is correct, proper additions of salts to the diet may contribute to the reduction of silica urolithiasis.

A more detailed account of these experiments will be published in the near future.

Vitamin B_{12} in Marine Fish

IN the course of a comparative investigation of the vitamin contents of different organs from fish[1], a rather interesting relative distribution, and in some cases unusually high concentrations, of vitamin B_{12} were observed. As the importance of vitamin B_{12} in marine ecology has been emphasized in recent reports[2-6], a brief account of the main findings is given in this communication.

Vitamin B_{12} was determined by microbiological assays with *Lactobacillus leichmannii*. To ensure that the growth-promoting activity measured was derived from vitamin B_{12}, checks were carried out by paper chromatography.

Although most organs have been investigated the complete results cannot be reported here. In Table 1 are shown the results of analyses of: muscle, kidney, liver and heart from some species. The most striking results are the frequent high values for vitamin B_{12} in the heart: single values up to 5 μgm. vitamin B_{12} per gm. fresh weight (20·8 μgm. per gm. dry weight) were found in hearts from the pollack (*Gadus pollachius*). So far as we know such high concentrations are very unusual in any natural source[8]. Another interesting result was the relation between the vitamin B_{12} content of liver and heart. In some cases the heart showed up to 150 times the value for the liver in the same fish. Normally, kidney and liver are recognized as the organs richest in vitamin B_{12}[7], but the present findings show that in fish the heart often contains the highest concentration. Tarr *et al.*[8] found in the kidney of the sockeye-salmon 18 μgm. vitamin B_{12} per gm. solids. Several other organs from this fish were also investigated, but unfortunately not the heart. In none of the species I investigated were such values for kidneys encountered.

Table 1. THE VITAMIN B_{12} CONTENT OF SOME ORGANS FROM FISHES

Species	μgm. vitamin B_{12} per gm. fresh weight			
	Muscle	Kidneys	Liver	Heart
Cod (*Gadus morrhua*)	0·005	0·045	0·045	1·85
Coalfish (*Gadus virens*)	0·035	0·070	0·14	0·50
Pollack (*Gadus pollachius*)	0·018	0·16	0·33	4·25
Haddock (*Gadus aeglefinus*)	0·018	0·32	0·067	2·58
Ling (*Molva molva*)	0·006	0·20	0·11	0·26
Tunny (*Thunnus thynnus*)	0·037	0·35	3·53	0·85
Plaice (*Pleuronectes platessa*)	0·022	0·37	5·00	0·81

So far the general picture seems to be that undernourished fish with very fat livers show low values for vitamin B_{12} in the livers and often very high values for the heart. Fat fish with 'normal' livers usually show the highest values for this organ, although high concentrations are also encountered in the hearts.

The results from the plaice (*Pleuronectes platessa*) deserve some comments. This fish lives in shallow waters where both the sea and most of its food may be expected to contain relatively high concentrations of vitamin B_{12}. It is therefore interesting to note the relatively high average value for the liver from this fish. Actually, in one of the samples from plaice the liver contained 8 μgm. vitamin B_{12} per gm. fresh weight (50 μgm. per gm. fat-free dry weight).

The results emphasize the position of the fish in the turnover of vitamin B_{12} in marine life. A detailed account of this work will be published elsewhere.

Deoxyribonuclease Activity and Deoxyribonucleic Acid Synthesis in Normal, Regenerating, Precancerous and Cancerous Rat Liver

INCREASE in the rate of deoxyribonucleic acid synthesis is a biochemical characteristic of hyperplastic growth. Whereas the rate of growth under normal conditions is under rigorous control, malignant growth may be characterized by the impairment of this kind of control. Since deoxyribonucleic acid synthesis is necessary for cell division, it is possible that this control may be exercised by the regulation of deoxyribonucleic acid metabolism. The purpose of this communication is to direct attention to a number of observations which, taken together, seem to indicate that deoxyribonuclease may be involved in such regulation.

In previous experiments[1,2] a close correlation between the activity of a deoxyribonuclease with *p*H optimum close to 5 and growth-rate or rate of synthesis of deoxyribonucleic acid has been demonstrated in normal tissues; increase in growth-rate was in all cases studied associated with increase in the level of deoxyribonuclease activity per cell. In contrast to this pattern in normal tissues, a lack of correlation between growth-rate and deoxyribonuclease activity was found in a series of malignant human and animal tissues[3]. The deoxyribonuclease activities of the tumours were approximately equal to, or lower than, those found in the tissues of origin.

In the search for an explanation of these apparent differences between normal and malignant growth, a systematic study has been made of the deoxyribonuclease activity in rat liver in various types of normal and malignant growth. Such a study makes possible a comparison of these various conditions in a single organ. Male Sprague–Dawley rats, weighing 250–300 gm., were used. The enzymic activities were determined in normal adult liver, in regenerating liver after partial hepatectomy, and in precancerous and cancerous livers, where the tumour was induced by feeding a rice diet containing 0·06 per cent *p*-dimethylaminoazobenzene[4] and supplemented with carrots. After three months, casein was added to the diet. The deoxyribonucleic acid phosphorus content and deoxyribonuclease activities were determined as described previously[5].

Table 1 is a summary of some of the results. Compensatory hyperplasia after partial hepatectomy is accompanied by an increase in deoxyribonuclease activity; the increase is very rapid and is observed

Table 1. Deoxyribonuclease Activity and Deoxyribonucleic Acid Phosphorus Content in Normal, Regenerating, Precancerous and Cancerous Rat Liver

* DNAP, deoxyribonucleic acid phosphorus.

† DNase (deoxyribonuclease) activities were determined by incubating tissue homogenates with calf thymus deoxyribonucleic acid at *p*H 5·25, adding trichloracetic acid – lanthanum acetate and centrifuging. The increase in deoxypentose in the supernatant was determined colorimetrically (ref. 5) and from this the amount of deoxyribonucleic acid phosphorus was calculated. The deoxyribonuclease activities are expressed as μgm. deoxyribonucleic acid phosphorus liberated per hr. per μgm. tissue deoxyribonucleic acid phosphorus or per total organ.

‡ Diffuse tumour infiltration.

§ Excised solid hepatoma.

as early as 12 hr. after operation. A high level of deoxyribonuclease is also found in rats on the *p*-dimethylaminoazobenzene diet. It is observed after 14 days, and approximately the same level is found at 60 days. After 90 days the value gradually decreases. The lowest values are found in the hepatoma. The deoxyribonuclease activity of this tissue is considerably lower than that of normal adult liver.

The growth response to partial hepatectomy in terms of deoxyribonuclease increase is very rapid. At 36 hr. after the operation, the remaining fragment of liver has a total deoxyribonuclease activity approximately equal to that of the intact organ, whereas during the same time interval only a fraction of new deoxyribonucleic acid has been synthesized (Table 1). The figures indicate that the peak-rate of deoxyribonucleic acid synthesis occurs somewhere between 39 and 44 hr. after partial hepatectomy. The prolonged stimulation of growth exerted by *p*-dimethylaminoazobenzene is associated with higher levels of deoxyribonuclease during the early stages of the carcinogenic process. The induced hepatoma, however, appears to have lost the capacity to respond to the continuous growth stimulation with an increase in deoxyribonuclease activity.

These findings seem to be in harmony with the protein deletion hypothesis put forward by Miller and Miller[6]. During precancerous stages, there is an accumulation of protein-bound derivatives of the azo dye in the rat liver. This seems to cause hyperplasia, which is accompanied by increase in cellular deoxyribonuclease activity. This increase appears to be a general reaction of the normal cell to a growth stimulus[1,2]. Gradually, however, a new type of cell, the cancer cell, appears, lacking, *inter alia*, the protein fractions which in the normal rat liver cell are bound to derivatives of the dye[6]. It is conceivable that some of these protein fractions might be concerned with deoxyribonuclease synthesis.

In summary, it can be said that in the rat liver during non-malignant growth increased rate of deoxyribonucleic acid synthesis is accompanied by increased deoxyribonuclease activity. The malignant cell is characterized by considerably increased rate of deoxyribonucleic acid synthesis[7] and subnormal deoxyribonuclease activity. During the carcinogenic process induced by *p*-dimethylaminoazobenzene, the early stages are associated with increased deoxyribonuclease activity, which decreases during the later phases of this process.

A detailed report on these findings and parallel histological changes will be published elsewhere.

I thank Drs. C. P. Rhoads, George Bosworth Brown and M. Earl Balis for encouragement and interest. A grant from the American Cancer Society and the Swedish Cancer Society is gratefully acknowledged. This investigation was supported in part by funds from the National Cancer Institute, National Institutes of Health, Public Health Service (Grant *CY*-3190), and from the U.S. Atomic Energy Commission (Contract No. *AT*(30-1)-910).

Importance of Zinc for the Growth of Surface-Culture of *Mycobacterium tuberculosis* var. *bovis* and Large-scale Production of Tuberculin Purified Protein Derivative

DURING the past eight years of large-scale cultivation of *Myc. tuberculosis* var. *bovis* '*AN*5' on the Dorset–Henley synthetic liquid medium[1,2] for the production of tuberculin purified protein derivative, from time to time and especially during the past two years we have met serious difficulties due to premature sinking of the pellicles, about 3–6 weeks after inoculation (the normal time before harvesting being 8 weeks). Growth came to a standstill and losses in tuberculin production were substantial.

We checked several crucial points in the procedure, including the possibility that toxic products, for example peroxide, developed during autoclaving. We also introduced some improvements. By placing the penicillin flasks, in which the pellicles are grown, on a slant instead of horizontally, condensed moisture was prevented from dripping down. In this way the piercing of holes in the pellicles by water drops was avoided. By introducing in the inoculation scheme more natural media, such as Stonebrink's egg–pyruvic acid medium and Sauton's potato medium, we got better seed material. Nevertheless, the main cause of sinking still remained undetected and we turned our attention to trace elements, which had previously been neglected in checking the medium constituents.

L. A. Baisden[3] recommended the addition of many elements to the Dorset–Henley medium, which is composed of: L-asparagine, dipotassium hydrogen phosphate, trisodium citrate, magnesium sulphate, ferricitrate, glucose and glycerine. This was mainly because many brands of asparagine do not contain the impurities necessary for good growth of *Mycobacterium* cultures. Drea and Andrejev[4] pointed out some essential elements but they considered several others, including zinc and manganese, unessential.

A striking result of the investigations of Williston *et al.*[5] on the reasons for the premature sinking of some of their BCG cultures on Sauton media was the detection of the favourable effects of traces of zinc, present in some of their glycerine batches due to corrosion of galvanized containers. Similar results were obtained by Loginova[7].

Williston *et al.*[5] recommended the addition of both zinc and manganese, even if traces of these elements were present in the other constituents of the medium. We therefore investigated the effects of zinc on our bovine *AN*5 strain on the Dorset–Henley medium.

Zinc estimations, carried out since April 1958 on our glycerine batches and on complete culture medium revealed that less than 2 μgm./ml. was present. Manganese, often encountered in natural asparagine and probably in ferricitrate, was present, at concentrations of about 1–3 μgm./ml. medium.

We therefore added to our media: 10 μgm. zinc/ml. (60 flasks); 10 μgm. zinc + 2·5 μgm. manganese/ml. (5 flasks); 10 μgm. zinc + 2·5 μgm. manganese + 0·35 μgm. cobalt/ml. (5 flasks). The elements were added as A.R. sulphate, chloride and chloride respectively. Five flasks with non-enriched media served as controls.

We used cobalt (Williston *et al.*[5] were doubtful about its effect on growth) to neutralize peroxide which might be formed by autoclaving Mn^{++} and citrate[6]. Sinking occurred in the controls after about 3 weeks, while the other inoculates grew satisfactorily. The pellicles grown on the three kinds of enriched media appeared normal at the time of harvesting, and were indistinguishable by eye from each other. Similarly, the addition of more zinc (20 μgm. zinc + 2 μgm. manganese + 0·35 μgm. cobalt) gave excellent results.

It must be pointed out that pellicles of the human strains *DT*, *C* and *PN* were slightly less apt to sink than those of the bovine strain. Human strain pellicles did not sink on the zinc-deficient media on which bovine pellicles did, though the growth was not so good as on media to which zinc had been added.

The yields of tuberculin from all the enriched batches were about 1·5–2 times those from sinking cultures, and equal to, or perhaps slightly better than, from our former successful cultures in which trace-elements were not investigated.

The colour of the protein precipitate from media enriched with zinc is strikingly whiter than that from sinking cultures. This led us to suppose that possibly the proportion of the almost white '$A + B$' proteins, known for their greater specificity in the intradermal test[8], might be higher in the former case.

Tested on guinea pigs sensitized with mammalian tuberculosis, the potency of the 'zinc-added' tuberculin (15 *TU* per injection) proved to be significantly higher than that of tuberculin from sinking cultures. The average swelling diameters were respectively 13·5 and 11·1 mm. On the other hand, the reactions provoked by 1,500 *TU* on avian-sensitized guinea pigs were similar for both products. Higher specificity is thus indicated as well.

Confirmation of this was provided by chromatography[9]: the percentage of '$A + B$' protein in 'zinc-added' tuberculoprotein was about 2–3 times that in tuberculoprotein from sinking cultures.

Immunology and Chromatography in Taxonomic Studies on Gallinaceous Birds

I HAVE recently described a correlation between antigenic properties and hæmoglobin composition of the blood of some passerine birds[1]. The relationships of red-cell antigens and of hæmoglobins suggested some possible phylogenetic affinities among these birds, since these characters are gene-determined. There was very little intraspecific variability.

An immunological analysis of red-cell antigens and a chromatographic analysis of pectoral muscle of three species of gallinaceous birds have been made. The three species, *Numida meleagris*, *Gallus gallus* and *Meleagris gallopavo*, belong, according to Wetmore's classification[2], to three different families of the order Galliformes, sub-order Galli, superfamily Phasianoidea.

The genetic properties of red-cell antigens and the inferences that can be drawn from immunological relationships on phylogeny and systematics have been largely discussed[3]. Also the application of paper partition chromatography has proved useful for understanding phylogenetic relationships. Buzzati-Traverso and Rechnitzer[4], Buzzati-Traverso[5], Micks[6] and Fox[7] have shown that chromatographic patterns of different species show constant differences, independently of environmental conditions, and that their similarities run parallel to their phylogenetic affinities.

The anti-erythrocytes sera of the three species of birds have been obtained from rabbits; the specific antigens have been separated from the common ones by absorption, and titrations have been made in serial dilutions at 37° C. The titres are given in Table 1. Every species possesses: (1) specific antigens; (2) antigens common to the other two species; (3) antigens common only to one of the other two. There is greater immunological affinity, that is, more common antigens, between *Meleagris gallopavo* and

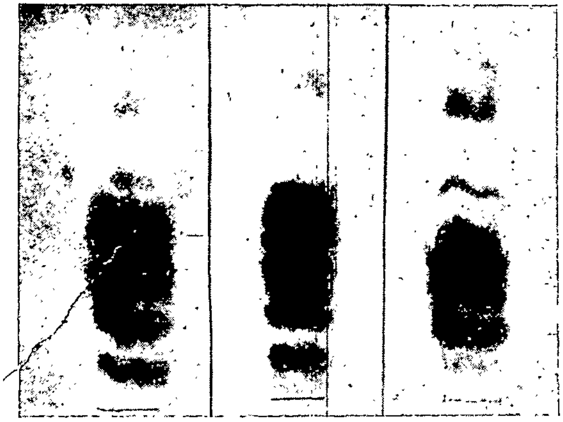
Table 1

Antiserum	Absorbing cells	Test cells		
		Gallus	*Numida*	*Meleagris*
Gallus	—	1/1,280	1/80	1/40
	Numida	1/640	—	1/20
	Meleagris	1/640	1/20	—
Numida	—	1/40	1/5,120	1/320
	Gallus	—	1/640	1/160
	Meleagris	1/20	1/40	—
Meleagris	—	1/80	1/1,280	1/1,280
	Gallus	—	1/640	1/320
	Numida	1/10	—	1/320

Numida meleagris than between these two species and *Gallus gallus*.

For ascending paper partition chromatography the following technique has been used. Pectoral muscle is homogenized in a tissue grinder with distilled water (1 muscle : 2 distilled water); then, after centrifugation, the supernatant is deproteinized by 20 per cent trichloracetic acid, and the excess of the latter is removed by ether. The liquid is concentrated (1/3) by evaporation at 2° C. Whatman No. 1 filter paper is used. The solvent consists of 1 part of 1 per cent ammonia and 2 parts of *n*-propanol. The chromatograms are sprayed with a 0·2 per cent solution of ninhydrin in 95° ethanol.

Chromatographic patterns of pectoral muscle of several individuals of the same species were identical.



Numida *Meleagris* *Gallus*

Fig. 1

As can be seen in Fig. 1, there is greater similarity between the chromatograms of *Numida meleagris* and *Meleagris gallopavo* than between these two species and *Gallus gallus*. Consequently, this chromatographic similarity confirms the closer immunological affinity between *Numida* and *Meleagris*.

The Heterozygous Carrier in Galactosæmia

GALACTOSÆMIA is a hereditary disorder of carbohydrate metabolism characterized by vomiting, diarrhœa, jaundice, poor weight gain and malnutrition during early infancy. Mental retardation, cataracts and cirrhosis of the liver are common complications. The diagnosis can be made by a markedly elevated galactose tolerance test, and identification of galactose in the urine. In 1956, Schwarz, Goldberg, Komrower and Holzel[1] showed that galactose-1-phosphate accumulates in the erythrocytes of galactosæmic children if they receive galactose or milk. This indicated that galactokinase must be present in such individuals. In the same year, Isselbacher, Anderson, Kurahashi and Kalckar[2] demonstrated a deficiency of galactose-1-phosphate-uridyl transferase in the erythrocytes of these children. This indicated that the site of the metabolic block in this disease was at the step of:

$$\text{Galactose-1-PO}_4 + \text{UDP glucose} \rightleftharpoons \text{UDP galactose} + \text{glucose-1-PO}_4$$

The frequent occurrence of this condition in siblings and among the offspring of consanguineous matings together with its equal distribution in both sexes suggest that galactosæmia is probably transmitted by a single autosomal recessive gene. In this situation, one would expect the disease to occur only in persons who receive two of the abnormal genes, one from each parent. If one individual is heterozygous for the condition, he will usually be free of clinical symptoms. Careful biochemical studies, however, might reveal minor departures from the norm[3]. Holzel and Komrower[4] undertook galactose-tolerance tests among parents, siblings, and near relatives of six families with known cases of galactosæmia. They found the response to be abnormal in a number of the relatives tested, but this was not a consistent finding among all the individuals who should be heterozygous. Furthermore, in the majority of cases, usually only one of the parents showed a lowering of the galactose-tolerance test.

The purpose of the present communication is to report on the measurement of galactose-1-phosphate-uridyl transferase activity in five galactosæmic families. In each instance, the diagnosis of galactosæmia was established by identifying the presence of galactose in the urine through paper chromatographic separation or by the osazone and mucic acid test or both. Galactose-1-phosphate-uridyl transferase activity was assayed by the method of Anderson, Kalckar, Kurahashi and Isselbacher[5], as follows. Red blood cells of fasting venous blood were washed twice with a double volume (twice the volume of the packed cells) of 0·9 per cent sodium chloride and hæmolysed by the addition of an equal volume of cold distilled water. Hæmolysate was then incubated with uridine diphosphoglucose (UDPG), galactose-1-phosphate, and *tris* glycine buffer for 30 min. at 37° C. For each sample, a control was run where no galactose-1-phosphate was added to the substrate. After incubation, diphosphoglucose was determined in heat-inactivated hæmolysates by means of diphosphoglucose dehydrogenase. The difference between the measurements of diphosphoglucose in the sample and control represents the amount of it consumed due to the activity of galactose-1-phosphate-uridyl transferase. Uridine diphosphoglucose pyrophosphorylase activity was

Range	2·8–7·0	1·7–5·5	0–1·07

also determined to assure that the blood sample and the hæmolysate were properly handled.

Results for eleven normal controls, twelve heterozygotes (nine were parents, two were offspring, and one was both a parent and an offspring of patients with galactosæmia) and nine galactosæmics are tabulated in Table 1 and summarized in Table 2. It would appear that about half the levels of galactose-1-phosphate-uridyl transferase among the heterozygotes lie below the range of the normal controls, and the difference between the means is significant at the 0·05 level.

All the blood samples were taken in a fasting state. A dose of 40 gm. of D-galactose was given by mouth to four of the heterozygotes and 1·25 gm./kgm. body-weight to two of the affected children. In Table 3 are listed the galactose and galactose-1-phosphate-uridyl transferase levels in whole blood and the erythrocytes respectively before, 1 hr. and 2 hr. after this load. There appears to be a decrease in the galactose-1-phosphate-uridyl transferase activity following the load in both of the affected children and in two of the four heterozygotes. The possible significance of these findings is being further evaluated.

While the results in a single individual must be interpreted with caution, the lower values of galactose-1-phosphate-uridyl transferase found in a group of heterozygotes offer confirmation for the view that the lack of this enzyme is the primary biochemical lesion in galactosæmia. Furthermore, the decrease of this enzyme in the heterozygote with one abnorm gene and its virtual absence in the homozygote wit two abnormal genes extend the possibility of detec ing heterozygous carriers biochemically, as in t case of abnormal hæmoglobins[6], phenylketonuri and glycogen storage disease of the liver (Hsi D. Y. Y., and Gawronska, E., unpublished work).

Table 3. BLOOD GALACTOSE LEVEL AND GALACTOSE-1-PHOSPHATE-URIDYL TRANSFERASE ACTIVITY FOLLOWING THE ADMINISTRATION OF 40 GM. OF D-GALACTOSE TO FOUR HETEROZYGOTES, AND 1·25 GM./KGM. BODY-WEIGHT TO TWO GALACTOSÆMIC CHILDREN

Time (hr.)	Galactose (mgm. per cent)			Galactose-1-phosphate-uridyl transferase (units/gm./kgm.)

Fomes noxius, a Thiamine-deficient Fungus

THE tropical brown root disease, caused by *Fome noxius* Corner[1], is of widespread occurrence and i found on the roots of a great number of tropica plants such as *Artocarpus*, *Cinchona*, *Cacao*, *Coffea* *Grevillea*, *Erythrina*, *Eriodendron*, *Elaeïs*, *Hevea* *Thea*, *Theobroma* and of forest trees.

The correct scientific designation of the fungus i not quite clear, and various authors have recorded i under different names : for example, Petch[2] refers t it as *Fomes lamaensis* (Murr.) Sacc. ex Trott., whil Roger[3] describes it as *Phellinus lamaensis* (Murr. Sacc. ex Trott. In this communication Corner' designation is followed.

The distinguishing characteristic of the brown roo disease is the fine brown fungus mycelium whic covers the roots of affected plants like a sheath ; soi particles and small stones adhere to this brow mycelium cover. The fungus later forms a thic brown or blackish felted crust on the affected root The outer layer of the crust is brittle and blackish i appearance but the mycelium of the inner laye remains mostly brown. Under this crust the disease bark disintegrates and the wood is penetrated by network of branching brownish-black lines or b bands of the mycelium.

So far as can be ascertained from available litera ture[4], *Fomes noxius* has not yet been grown o investigated in pure culture.

As *Fomes noxius* belongs to the group of th Hymenomycetes which is known to be partially o totally deficient in thiamine (aneurin, vitamin B_1) the requirements of this fungus in this particula respect have been investigated.

Attempts to grow *Fomes noxius* in purely artificial media, as those of Czapek, Fries, Richard or Knop, were unsuccessful. However, as soon as organic materials, such as malt extract, yeast extract, decoc-ion of wood of *Hevea brasiliensis* or of fresh *Hevea* eaves were added, luxuriant growth of the fungus was observed. The fungus also grows well on sterilized pieces of fresh rubber wood and of the roots of rubber, tea or cocoa plants.

Our experiments were carried out in 500-ml. Jena Erlenmeyer flasks, each series consisting of ten asks. All experiments were replicated three times, nd the chemicals used were of analytical grade.

In order to obtain a uniform inoculum for these xperiments, the fungus was pre-cultivated for 42 ays on sterilized pieces of fresh rubber wood. The mycelium suspension was prepared by adding 100 ml. of sterile distilled water to each flask followed by igorous shaking. The Erlenmeyer flasks containing the culture media were then inoculated by the wet method, each flask with 0·5 ml. of the mycelium suspension, and the cultures then incubated for 28 days t 27° C.

Knop solution containing 10 gm./l. of vitamin-free lucose was used as basic medium for these experiments.

able 1. *p*H AND MYCELIUM DRY WEIGHTS IN MGM. OF *Fomes noxius* N KNOP-GLUCOSE MEDIUM WITH AND WITHOUT ASPARAGINE, HIAMINE, THIAZOLE OR PYRIMIDINE AFTER 28 DAYS AT 27° C.

Culture medium, Knop +	*p*H of culture medium at beginning	at end	Mycelium per flask (dry weight in mgm.)
10 gm./l. glucose	5·0	4·7	1·8
10 gm./l. glucose 1 gm./l. asparagine	5·0	3·5	3·3
10 gm./l. glucose 0·5 mgm./l. pyrimidine	5·2	5·1	2·4
10 gm./l. glucose 0·5 mgm./l. thiazole	5·2	4·6	3·0
10 gm./l. glucose 1 gm./l. asparagine 0·5 mgm./l. pyrimidine	5·2	3·3	10·4
10 gm./l. glucose 1 gm./l. asparagine 0·5 mgm./l. thiazole	5·3	3·8	12·2
10 gm./l. glucose 0·5 mgm./l. pyrimidine 0·5 mgm./l. thiazole	5·0	4·8	2·7
10 gm./l. glucose 1 gm./l. asparagine 0·5 mgm./l. pyrimidine 0·5 mgm./l. thiazole	5·3	4·8	288·6
10 gm./ml. glucose 1 mgm./l. thiamine	4·9	4·8	3·8
10 gm./l. glucose 1 gm./l. asparagine 1 mgm./l. thiamine	5·2	5·1	291·2
10 gm./l. glucose 10 gm./l. malt extract	5·2	3·8	337·0
10 gm./l. glucose 10 gm./l. yeast extract	5·4	8·2	346·2

It will be seen from the results of this experiment hat *Fomes noxius* is unable to synthesize either the whole thiamine molecule or its two constituent parts, pyrimidine and thiazole, but is able to combine pyrimidine and thiazole into thiamine. It thus differs from *Fomes lignosus*[5], which has been shown to be able to synthesize at least one part of the thiamine molecule, namely, thiazole. *Fomes noxius* is further unable to grow on pure Knop solution with glucose and thiamine, or with glucose and pyrimidine plus hiazole, if asparagine is absent. It seems, therefore, hat *Fomes noxius* is unable to make use of nitrogen upplied in the form of nitrate.

Work in progress should show whether *Fomes noxius* is able to replace asparagine as a source of nitrogen by other forms of organic nitrogen, or by ammonium.

Confusion between *Gromia oviformis* and *Allogromia ovoidea*

Gromia oviformis Dujardin, 1835, and *Allogromia ovoidea* Rhumbler, 1903, are marine rhizopods with which the general zoologist is usually acquainted. The former is well known because of its abundance in the inter-tidal zones around the rocky parts of the British coasts, and reference has been made to it in some text-books of invertebrate zoology and protozoology. *Allogromia ovoidea*, although less well known as a living animal, has been prominently figured on many occasions in standard zoological text-books. During the past fifty years a great deal of confusion has arisen concerning these two protozoans, as a result of which incorrect names are now given in several text-books and standard works of reference.

The confusion which exists is shown in the following names given by authors to text-figures, all of which are of the same animal and based on an original by Schultze[1]: *Gromia oviformis* Dujardin[2], *Allogromia ovoidea* Rhumbler[3], *Gromia oviformis* Schultze (= *G. ovoidea* Rhumbler)[4], *Allogromia oviforme*[5,6], and *Allogromia oviformis*[7–10]. All except the second in this list, namely, *Allogromia ovoidea* Rhumbler, are incorrect, and as a result of such misdeterminations the belief has arisen that the two animals being discussed are one and the same. Hence *Gromia oviformis* Dujardin, 1835, is now incorrectly recorded in the "Plymouth Marine Fauna"[11] as "*Allogromia oviformis* (Dujardin) [Jepps, 1926, as *Gromia*]".

A short account of the events relevant to this situation partly explains how the confusion has arisen. Dujardin[12] described and figured a new protozoan under the name *Gromia oviformis*. Schultze[1] later described and illustrated a form as *Gromia oviformis* Dujardin, 1835, which was a straightforward misidentification. This view is supported by the fact that in the same publication Schultze describes as new *Gromia dujardinii*, the illustration of which leaves no doubt that it is the same as *Gromia oviformis* Dujardin, 1835. Here then seems to be a case of double misidentification, leaving an animal described and figured but incorrectly identified as *Gromia oviformis*. This situation existed until Rhumbler[13] recognized *Gromia oviformis* Dujardin, 1835, as a form with filose pseudopodia, and *Gromia oviformis* Dujardin of Schultze, 1854 (the misidentified form), as a form with granulo-reticulose pseudopodia. Rhumbler proposed that the filose forms, namely, *Gromia*, be placed in the Class Filosa, and that the granulo-reticulose forms be included in a new genus, *Allogromia*, within the Class Reticulosa. Rhumbler then erected the new name *Allogromia ovoidea* for that animal misidentified and illustrated by Schultze in 1854.

It was not until 1934, when De Saedeleer[7] discussed Rhumbler's work, that a further change of name was accompanied by any comment, although incorrect names had been used before this date[4,6,8]. De Saedeleer agreed that the *Gromia oviformis* Dujardin of Schultze should be *Allogromia*, but considered, without giving reasons, that a change of the specific name from *oviformis* to *ovoidea* was wrong. He proceeded, therefore, to refer to *Allogromia oviformis*, an unfortunate choice in view of the confusion that has arisen from its usage. According to article 31 of the International Rules of Zoological Nomenclature[14] "a specific name which undoubtedly rests upon an error of identification cannot be retained for the misdetermined species even if the species in question are afterwards placed in different genera". De Saedeleer's claim, therefore, cannot be upheld, and *Allogromia ovoidea* Rhumbler is the correct name for the misidentified *Gromia oviformis* of Schultze, with which the quite different *Gromia oviformis* Dujardin, 1835, is not to be confused.

Quite apart from this account of names, the systematic positions of *Gromia* and *Allogromia* are by no means understood. Sometimes referred to as gromoid forms, they are regarded by some workers as Foraminifera and by others as Testacea. The problem will only be resolved by a fuller understanding of the biology of the animals, of their pseudopodial organization, and of their life-cycles. An extension of the works of Jepps[15] and Arnold[16] to other closely related Testacea and Foraminifera is particularly desirable at this stage in order to give a firmer basis for the distinction between these two groups. At the moment the systematic position depends largely on whether a form produces anastomosing, granular pseudopodia (*Allogromia* and members of the Foraminifera) or pseudopodia which do not, or rarely, anastomose, and are non-granular (*Gromia* and members of the Testacea). Such differences are not always clear cut, and so far there has been no functional interpretation of them. As there are many workers who consider these gromoid animals to be living representatives of a primitive group from which the Foraminifera may have evolved, the answers to these problems should help to clarify the origin of this large and morphologically very diverse order of the Protozoa.

Sex Ratio in the Golden Hamster before Uterine Implantation

MOST mammalia have a secondary sex ratio nea 100 : 100 with a slight excess for the male sex. A male- and female-determining spermatozoa are bein produced in equal numbers, the primary sex rati would also be 100 : 100, provided that the two kind of sperms are equally able to fertilize. However, a higher mortality-rate in male than in female embryo has been observed in stages in which the sex may be anatomically recognized[1], and is also generally supposed to operate in preceding stages. Based upon this a primary sex-ratio of 150 : 100 has been calculated[1] which must imply a higher frequency of successful fertilizations performed by male- rather than by female-determining spermatozoa.

In order to estimate the sex ratio in as close agreement as possible with the primary one we have determined the sex of a number of embryos before implantation by making use of the morphological differences between the X- and Y-chromosomes. This was possible in the golden hamster, *Mesocricetus auratus*, as the sex chromosomes, which in this species are larger than the autosomes, may be distinguished from each other[2].

Mated females were killed 80–90 hr. after copulation, at which time the embryos were in the blastocyst stage, containing mostly 20–32 cells. The blastocysts were collected by flushing the uterine horns with Tyrode solution, and treated with a 0·45 per cent saline at 37° C. for 15 min. in order to obtain better spreading of the chromosomes at squashing[3]. The blastocysts were then fixed for some hours in absolute alcohol–acetic acid 3 : 1, stained for 15 min. in acetic-lacmoid solution[4], and mounted as squash preparations in neutral Canada balsam.

Using a Zeiss phase-contrast oil immersion objective (mag. 100 ×, N.A. 1·25) camera lucida drawings were made of the chromosomes of well-spread metaphase plates, and the occurrence of X–X- and X–Y-combinations respectively was determined.

As the frequency of metaphase plates was very low—about one plate in every third blastocyst—we introduced a pretreatment of the pregnant females with colchicine[5] in order to increase the number of cells in metaphase at killing. The animals were injected intraperitoneally with 0·025 mgm. colchicine per 100 gm. body-weight 5–8 hr. before being killed. This treatment increased the frequency of metaphases to about one plate per blastocyst, without obscuring the chromosomal morphology.

Until now 51 blastocysts from 39 hamsters have been classified according to sex. Of these, 33 were males and 18 females, giving a sex ratio of 183 : 100, which significantly deviates from 100 : 100 ($t^2 = 4{\cdot}41$, $p < 0{\cdot}05$). The experiments are being continued, and the results from more material will be published in due course.

Australian Discoveries of Emperor Penguin Rookeries in Antarctica during 1954-57

The emperor penguin (*Aptenodytes forsteri* Gray) breeds only around the coastline of Antarctica. Many decades elapsed between the time when the birds were first seen and the discovery of a breeding place. The first emperor rookery was discovered at Cape Crozier, on Ross Island, in October 1902 [1].

During Sir Douglas Mawson's Australasian Antarctic Expedition, 1911–13, a rookery was discovered at Haswell Islet and another suspected near the Shackleton Ice Shelf[2]. The latter has been confirmed in 1957 by Russian workers operating from Mirny (personal communication). The German Südpolar Expedition saw large numbers of juveniles in December 1902, when beset near the monolith now known as Gaussberg. However, the presence of a rookery here is doubtful, and the chicks may have come from Haswell Islet. Russian workers operating near Gaussberg in 1957 saw no sign of a rookery.

No further discoveries were made until 1948, when a Falkland Islands Dependencies Survey party found a small rookery on the Dion Islets, south of Adelaide Island, Graham Land[3]. In 1950, a larger one was discovered at Pointe Géologie, Terre Adélie, by a French party from Port Martin[4].

Since that time members of the Australian National Antarctic Research Expeditions have discovered five more emperor penguin rookeries. The first of these was found in October 1954 by a two-man sledging party, R. Dovers and G. Schwartz, approximately 50 miles west of the A.N.A.R.E. base Mawson. It is situated on the eastern side of Taylor glacier (67° 28′ S., 60° 53′ E.) and, unlike most emperor rookeries, is not on sea ice but on land. It contains more than five thousand breeding birds and, partly because of its geographical advantages and sheltered position, appears to have a relatively low chick mortality.

In May 1956 during a flight from Mawson westward to King Edward VIII Gulf, Dr. D. A. Dowie and Flight Sergeant J. Seaton, R.A.A.F., saw a smaller rookery, which was visited in the following spring. It is situated on the southern side of Fold Island (67° 20′ S., 59° 23′ E.) and contains nearly two thousand breeding birds. Studies carried out here in 1957 revealed a very high chick mortality.

The other three rookeries were all discovered during 1957. A very large group of birds was seen from the air by Flight Officer D. Johnston, R.A.A.F., in August 1957, 35 miles east of Mawson at approximately 67° 25′ S., 64° 00′ E. It was visited by K. B. Mather, D. Johnston and me on the next day, by aeroplane, and aerial photographs were taken. A fortnight later R. T. Lee and I visited the rookery by 'weasel'. A count made then confirmed the estimate, made from the photographs, of twelve thousand birds. Random sampling of the population revealed that 71 per cent of the birds were holding chicks. Approximately six hundred dead chicks were found lying on the ice, and probably many more had been buried by snow. Evidence of a great many broken and abandoned eggs was also found, and it may be concluded that at least twenty thousand breeding birds entered the rookery during the breeding season.

This rookery is situated on sea ice which is very thick and rough and is made stable by hundreds of grounded bergs in the vicinity. It is unusual in being about eight miles from the nearest group of islands (Douglas Islands) and 7–8 miles from the mainland. The bergs, however, act as islands do at other rookeries, holding the sea ice from breaking out during the breeding season. No land feature is near enough to give it a name, and it is therefore being named Auster rookery, after the plane from which it was first seen. A very large feeding hole was found six miles south of this rookery at the base of a tilted berg[3].

During September 1957 two more rookeries were sighted from the air by Flight Lieutenant P. Clemence, R.A.A.F. Neither has yet been visited. One is situated at Kloa Pt. (66° 37′ S., 57° 11′ E.), near Cape Boothby, 180 miles west of Mawson. Its size was estimated visually as five thousand when it was first sighted; but this has not been confirmed by any other method. It is situated on sea ice which is held in by a small group of islands.

In the same month, during a flight south-west from the A.N.A.R.E. base Davis in the Vestfold Hills, a

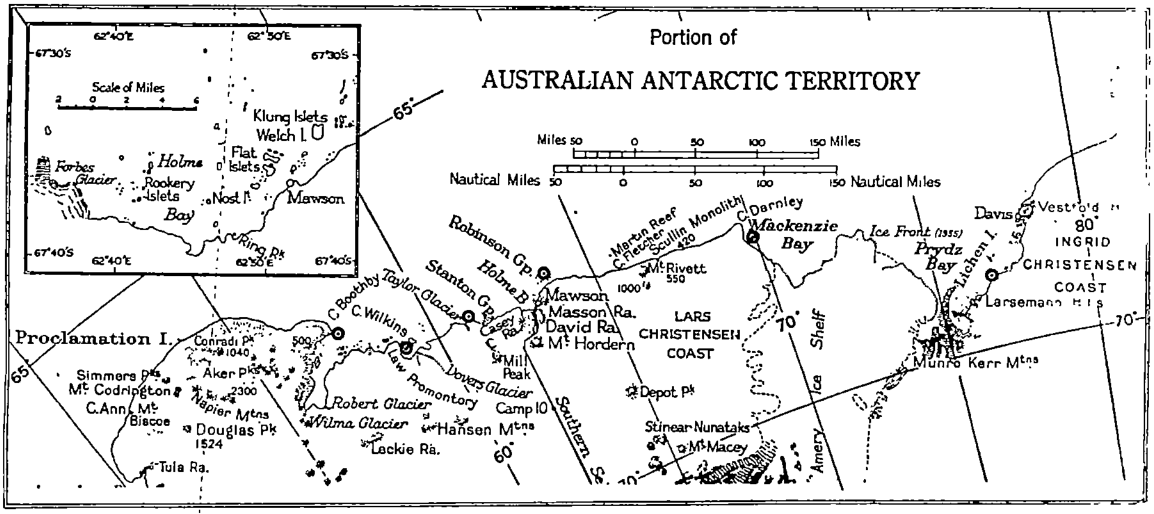

Fig. 1. Part of Australian Antarctic Territory, showing Emperor Penguin rookeries discovered by A.N.A.R.E. From west to east, Kloa Point, Fold Island, Taylor Glacier, Auster Rookery, Cape Darnley, and Amanda Bay

group of birds was seen on the sea ice near a glacier tongue between Davis and the Larsemann Hills (69° 14′ S., 76° 53′ E.). From aerial photographs taken then, the population at that time was estimated to be between one thousand and two thousand birds.

Other parties operating in Antarctica have also reported in personal communications recent discoveries of new emperor penguin rookeries. With the five discovered by A.N.A.R.E. parties it now seems that, although they are by no means numerous, emperor penguin rookeries are no longer a rarity.

Since this communication was drafted, a sixth rookery has been discovered by members of A.N.A.R.E. It is situated in approximately 68° S., 69° 45′ E., among a large group of icebergs on the eastern side of Cape Darnley. It was discovered in August 1958 by Flight Lieutenant H. O. Wilson, R.A.A.F., during a flight from Mawson to Davis. The population is roughly estimated as 5,000.

The Tide at Shackleton

The sea tide has been measured at the Trans-Antarctic Expedition's Shackleton Base, on the Filchner Ice Shelf in the Weddell Sea. The ice shelf is afloat over some 500 fathoms of water, and is not thought to be aground anywhere within at least 15 miles; the nearest known land is more than 20 miles to the east. In the absence of any fixed point to which the tide could be referred, a Worden gravimeter was used as an altimeter. The gravimeter was placed in a cavern dug 18 ft. below the snow surface, and photographs automatically taken through the eyepiece every hour. A ten-minute exposure was used so as to average out the continual movement produced by unsteadiness of the ice shelf. The Worden is normally used by adjusting a micrometer head until a pointer seen through the eyepiece is in its zero position; in this work the micrometer was left untouched for many days at a time, and the displacement as photographed through the eyepiece was converted into a correction to the constant setting. In this way readings were obtained from August 8 until October 3, 1957. 145 readings were missed, mostly in the early stages and mainly in two big gaps; these were due to my carelessly dropping a key into the works when reloading the camera, and so fusing the lamp.

Allowance was made for the direct tidal variation of gravity (modified by earth tides) as tabulated by Coguel[1]; this produced what are referred to below as 'corrected readings'. Gravimeter drift was calculated by computing a mean reading at each sixth hour, using a formula which takes account of constituents up to sixth-diurnals; these values were then smoothed. The big gaps were filled by fitting a fifth- or seventh-degree polynomial, and using the curve of residuals. Sub-tabulation was then carried out at hourly intervals. Subtracting the 'corrected readings' from these drift values gave figures proportional to the height of the tide above mean sea-level.

These readings were then divided into two 29-day periods, sharing a common day—first, August 8–September 5, and secondly, September 5–October 3. Each period was then subjected to analysis by the method given in "The Admiralty Tide Tables"[2], with the results set out in Table 1. In the averaging, the first period is somewhat arbitrarily given half the weight of the second, because the readings have more gaps and the gravimeter drift was more erratic in the first period. Gravimeter readings were converted to heights by the usual Bouguer formula with an insignificant modification for the acceleration implied by the rise and fall.

Table 1. Shackleton Base. 77° 59′ S., 37° 10′ W.

	M_2		S_2		N_2	
	H	g	H	g	H	g
Period 1	2·14	157°	1·52	180°	0·32	150°
Period 2	1·98	160°	1·44	174°	0·34	148°
Mean	2·03	159°	1·46	176°	0·33	149

	K_1		O_1		M_4		MS_4	
	H	g	H	g	H	g	H	g
Period 1	1·06	348°	0·75	303°	0·02	179°	0·05	279°
Period 2	0·48	342°	1·02	325°	0·07	131°	0·04	206°
Mean	0·67	345°	0·91	319°	0·05	136°	0·04	235°

Central days: period 1, August 22, 1957; period 2, September 19, 1957. Standard time: 4 hr. west. Heights, H, are given in feet.

It can be seen that the constants derived from the two periods are in poor agreement for the diurnals, that the semi-diurnals are well determined, and that the quarter-diurnals are negligible. It is known that there is a spurious constituent of variable amplitude (of the order of 0·3 ft.) and period 40 hr., coinciding with the interval between visits to the cavern to re-load the camera. This is bigger than was expected; but for just that reason makes it plausible that there should be another spurious constituent large enough to produce serious interference with the diurnals, and of period 24 hr. The constants in Table 1 are tolerably compatible with other measurements in the South Orkneys and Graham Land as given by Roberts and Corkan[3], and are well placed to strengthen the co-tidal charts in a little-known area.

I am indebted to the Director of the Liverpool Observatory and Tidal Institute for help in the analysis, and also to Dr. G. P. Woollard of the University of Wisconsin for the loan of the gravimeter and to the British Petroleum Co. for the automatic camera. A full account of this work is to be published in "The Trans-Antarctic Expedition Scientific Reports".

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 17

INSTITUTE OF ACTUARIES (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. E. N. Mutch: "The Progress of Business Computers in Britain". (Further lecture on December 1.)

ROYAL INSTITUTE OF CHEMISTRY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 5.45 p.m.—Dr. David John Manners: "Recent Advances in the Structural Analysis of Polysaccharides".* (Meldola Medal Lecture.)

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. S. E. Goodall: Presidential Address.

Tuesday, November 18

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. D. A. Sholl: "The Randomness of the Brain".*

INSTITUTION OF ELECTRICAL ENGINEERS, MEASUREMENT AND CONTROL SECTION (in conjunction with the BRITISH NUCLEAR ENERGY CONFERENCE, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. W. Binns and Mr. W. J. Outram: "Electrification of the U.K.A.E.A. Industrial Group Factories".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE (in Committee Room 12, House of Commons, London, S.W.1), at 5.15 p.m.—Meeting of the General Committee. 5.30 p.m.: Discussion on "Railway Research and Development" initiated by General Sir Brian Robertson, Bt., G.C.B., G.B.E., K.C.M.G., K.C.V.O., D.S.O., M.C.

RESEARCH DEFENCE SOCIETY (in the Lecture Theatre, Zoological Society of London, Regent's Park, London, N.W.1), at 5.30 p.m.—Mr. Richard Fort, M.P.: "The Irrational in Public Life". (Twenty-seventh Stephen Paget Memorial Lecture.)

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. Hayes: "Bacterial Genetics and Gene Structure".* (Sixth of eleven lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on November 20, 25, 27, December 2 and 4.)

PLASTICS INSTITUTE, LONDON AND DISTRICT SECTION (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m.—Mr. A. B. Merriam: "Commercial and Cost Considerations in Injection Moulding". (Junior Lecture.)

Tuesday, November 18—Wednesday, November 19

INSTITUTION OF GAS ENGINEERS (at Church House, Westminster, London, S.W.1), at 9.30 a.m. daily—24th Autumn Research Meeting.

Wednesday, November 19

INSTITUTE OF METAL FINISHING (at the Charing Cross Hotel, Strand, London, W.C.2), at 10.15 a.m.—Symposium on "Technical Control in Electroplating".

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 2.30 p.m.—Discussion on "Atmospheric Chemistry".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. L. A. Longden: "Improving the Efficiency of the Mining Industry" (Cadman Memorial Lecture).

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, Portland Place, London, W.1), at 2.30 p.m.—Symposium on "Analytical Instrumentation Developed at Harwell".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Mr. H. F. Lydall: "The Long-Term Trend in the Size Distribution of Income".

INSTITUTION OF ELECTRICAL ENGINEERS, RADIO AND TELECOMMUNICATION SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. Redmond: "Television Recording—a Survey of the Problems and the Methods Currently in Use".

ROYAL MICROSCOPICAL SOCIETY (at Tavistock House South, Tavistock Square, London, W.C.1), at 5.30 p.m.—Mr. B. E. Juniper: "Electron Microscopy of Leaf Surfaces".

UNIVERSITY COLLEGE (in the Physiology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. D. A. Denton (University of Melbourne): "The Control of Secretion of the Transplanted Adrenal Gland".*

INSTITUTION OF MECHANICAL ENGINEERS, APPLIED MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Working Stresses and Factors of Ignorance".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at the Royal Society of Health, 90 Buckingham Palace Road, London, S.W.1), at 6.30 p.m.—Annual General Meeting. Discussion on "Institute Affairs" opened by Dr. C. C. Hall.

Thursday, November 20

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Lord Medway: "Navigation on the Wing in Total Darkness by means of Echo Among Swiftlets of the Genus *Collocalia* in Borneo". 5.5 p.m.—Symposium on "Chromatography and Taxonomy" opened by Dr. E. C. Bate-Smith, Dr. C. A. Wright, Dr. J. B. Harborne, Dr. A. T. R. Mattick and Dr. N. J. Berridge.

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Special General Meeting, Dr. H. Godwin, F.R.S.: "Late-glacial Deposits at Moss Lake, Liverpool"; Dr. H. Godwin, F.R.S., and Mr. E. H. Willis: "Radiocarbon Dating of the Late-glacial Period in Britain" (Studies of the Post-glacial History of British Vegetation, 14).

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting, followed by Prof. K. A. Hirsch: "Torsion-free Abelian Groups".

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. E. M. Shooter: "The Configuration of Proteins in Solution".* (Further lecture on November 27.)

INSTITUTION OF MINING AND METALLURGY (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5.10 p.m.—Scientific Papers.

ROYAL METEOROLOGICAL SOCIETY (in the Conference Hall, County Hall, London, S.E.1), at 5.30 p.m.—Dr. E. T. Pierce: "Thunderstorms". (Popular Lecture for Sixth-form Scholars. To be repeated on November 21.)

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. H. Humphrey: "What are γ-Globulins ?"* (Seventh of eleven lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on November 25, 27, December 2 and 4.)

BRITISH GLACIOLOGICAL SOCIETY (at Bedford College, Regent's Park, London, N.W.1), at 6 p.m.—Mr. D. W. Humphries: "Kilimanjaro and the International Geophysical Year".

INSTITUTION OF ELECTRICAL ENGINEERS, EDUCATION DISCUSSION CIRCLE (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "What is a Cultured Engineer ?"

ROYAL AERONAUTICAL SOCIETY (at the Institution of Mechanical Engineers, Birdcage Walk, London, S.W.1), at 6 p.m.—Second Lanchester Memorial Lecture.

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. I. L. Freeman: "Scientific Investigation of Clay Pits".

INSTITUTION OF ELECTRONICS (in the Assembly Hall of the University of London Institute of Education, Malet Street, London, W.C.1), at 7 p.m.—Mr. E. Wolfendale: "The Applications of Transistors in Communications and Control Equipment".

OIL AND COLOUR CHEMISTS' ASSOCIATION, LONDON SECTION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. E. F. Redknap: "Reactions of Drying Oils with Hydrocarbons".

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (at 17 Bloomsbury Square, London, W.C.1), at 7.30 p.m.—Scientific Meeting on "Applications of Gas Chromatography to Pharmaceutical Analyses".

Friday, November 21

BRITISH PSYCHOLOGICAL SOCIETY, OCCUPATIONAL PSYCHOLOGY SECTION (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Mr. T. Lupton: "Problems of Participant Observation".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Mr. George Lowe: "Navigating Across the Antarctic".

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Prof. L. L. Beranek: "The Transmission of Acoustic Waves Through Structures" (Thomas Hawksley Lecture).

ANTIQUARIAN HOROLOGICAL SOCIETY (at the Science Museum, South Kensington, London, S.W.7), at 7 p.m.—Mr. H. Alan Lloyd "The Baldewein Astronomical Clock of 1562".

ROYAL INSTITUTE OF CHEMISTRY (joint meeting with the EAST ANGLIA SECTION and CAMBRIDGE UNIVERSITY CHEMICAL SOCIETY, at the University Chemical Laboratory, Lensfield Road, Cambridge), at 8.30 p.m.—Dr. E. C. Barton-Wright: "The Chemistry of Wines and Spirits".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. F. C. Fraser: "Some Aquatic Adaptations of Whales and Dolphins".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH ASSISTANT, for work on adsorption of polar vapours on ionic crystals—Dr. F. C. Tomkins, Chemistry Department, Imperial College of Science and Technology, London, S.W.7 (November 19).

CHIEF (with a recognized university degree or equivalent in agricultural science and/or science (with physiology as a major subject) and/or veterinary science, and at least ten years postgraduate experience of research work and actively engaged in research in animal physiology, animal nutrition, animal husbandry, or allied subjects) OF THE ANIMAL PRODUCTION DIVISION—The Director, An Foras Talúntais (Agricultural Institute), 21 Earlsfort Terrace, Dublin (November 21).

LECTURER (able to teach organic chemistry to graduate level, conduct research, and preferably with industrial experience and the ability to direct work of postgraduate research students) IN ORGANIC CHEMISTRY in the Department of Chemistry and Biology, College of Technology, Liverpool—The Director of Education, City of Liverpool Education Committee, 14 Sir Thomas Street, Liverpool 1 (November 21).

SCIENTIFIC AIDE, Senior Research Officer grade (with a recognized university degree in agricultural science, at least five years postgraduate research experience in some branch of agricultural science, and preferably a competent knowledge of the organization of agricultural research and experimental work and the conduct of seminars or study courses)—The Director, An Foras Talúntais (Agricultural Institute), 21 Earlsfort Terrace, Dublin (November 21).

ASSISTANT, Grade B (preferably specializing in inorganic chemistry and also some applied science subjects), at Northampton College of Technology, TO TEACH CHEMISTRY up to Higher National Certificate and General B.Sc. standard—The Chief Education Officer, Borough Education Office, "Springfield", Cliftonville, Northampton (November 22).

LECTURER (with up-to-date industrial and/or research experience) IN INORGANIC CHEMISTRY—The Principal, Nottingham and District Technical College, Burton Street, Nottingham (November 22).

TECHNICIAN (preferably with an interest in complex physical apparatus) IN THE RADIOISOTOPES LABORATORY, Pollards Wood Research Station, Chalfont St. Giles, Bucks, to help with investigations on protein and nucleic acid biosynthesis—The Secretary, Chester Beatty Research Institute, Fulham Road, London, S.W.3, quoting "Isotopes" (November 22).

PRINCIPAL SCIENTIFIC OFFICER (with a first- or second-class honours degree in physics, physical chemistry or biochemistry, and at least three years postgraduate or other approved experience) at the Ministry of Agriculture, Fisheries and Food, London, for work on nuclear problems in relation to agriculture and food—The Civil Service Commission, 30 Old Burlington Street, London, W.1, quoting S.4900/58 (November 27).

CHAIR OF METALLURGY—The Registrar, The University, Manchester 13 (December 8).

GULBENKIAN RESEARCH FELLOW to investigate certain aspects of the teaching of physics or chemistry in schools—The Registrar and Secretary, The University, Bristol (December 15).

LECTURER or ASSISTANT LECTURER IN MATHEMATICS at the University of Malaya—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 15).

LECTURER or SENIOR LECTURER IN ANIMAL NUTRITION at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 15).

READER IN NUCLEAR ENGINEERING at Queen Mary College, Mile End Road, London, E.1—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 16).

SENIOR LECTURER IN MATHEMATICS at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 16).

ECOLOGIST (man, with a first- or second-class honours degree, and preferably with some knowledge of statistics), to join a team studying marine plankton, using continuous plankton recorders—The Officer-in-Charge, Oceanographic Laboratory, 78 Craighall Road, Edinburgh 6 (December 20).

LECTURER and an ASSISTANT LECTURER IN GENETICS—The Secretary of University Court, The University, Glasgow (December 31).

LECTURER IN VETERINARY PATHOLOGY AND BACTERIOLOGY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 31).

LECTURER (with a degree in engineering, preferably with honours, and experience and interest in the field of thermodynamics and heat engines) IN MECHANICAL ENGINEERING at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 31).

PROFESSOR OF PHARMACOLOGY—The Registrar, University Registry, Oxford (December 31).

DRUMMOND FELLOW (Senior or Junior, depending on qualifications) for Research in Nutrition—The Honorary Secretary, Drummond Trust, University College, Gower Street, London, W.C.1 (January 31).

ASSISTANT, Grade B (preferably with the ability to teach horticulture), TO TEACH BOTANY to B.Sc. (General) and G.C.E. Advanced and Ordinary levels—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

BIOCHEMIST, Basic grade (preferably with experience in routine medical biochemistry)—The Group Pathologist, Mental Hospitals' Group Laboratory, West Park Hospital, Epsom, Surrey.

BIOCHEMIST (with B.Sc. or M.Sc.), for research on insulin antagonisms in blood plasma—Dr. Vallance-Owen, Department of Medicine, University of Durham, King's College, Newcastle-upon-Tyne.

CHEMIST or BIOCHEMIST (preferably with a knowledge of carbohydrate chemistry) IN THE PHYSICAL CHEMISTRY DEPARTMENT, for research in immunological problems covering a wide range of interest—The Secretary, Animal Diseases Research Association, Moredun Institute, Gilmerton, Edinburgh 9.

RESEARCH ASSISTANT (with a good degree in either mathematics, physics or electrical engineering) IN THE SUB-DEPARTMENT OF COMPUTATION for work concerned with programming logical problems for a Pegasus computer—The Secretary and Registrar, The University, Highfield, Southampton.

SENIOR LECTURER (with good academic qualifications and suitable experience in the teaching of a branch of advanced mathematics) IN MATHEMATICS—The Secretary and Clerk to the Governors, Borough Polytechnic, London, S.E.1.

SENIOR SOIL CONSERVATION OFFICER (with a university degree or a recognized diploma in agriculture, and not less than ten years' experience in soil conservation work, preferably in East Africa) in Barbados to undertake the direction of conservation work—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD 63/28/06.

ZOOLOGIST (with a good honours degree in zoology and competent to plan zoological subjects for either television or film production), to carry out production and research work in conjunction with the Television and Film Unit located at the London Zoo, Regent's Park—The Secretary, Zoological Society of London, Regent's Park, London, N.W.1.

Is this what you need?

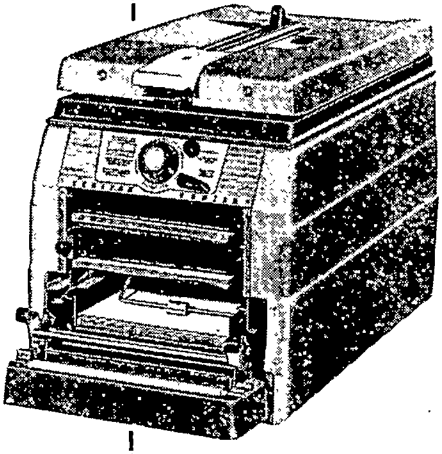
a simple copier

- ★ *that enables everyone to make his or her own copies*
- ★ *that copies everything, including pencilled notes and sketches*
- ★ *that gives you six copies in just over a minute for less than a shilling*
- ★ *that produces* dry *copies, ready for immediate use*
- ★ *that is self-contained*
- ★ *that takes up only a corner of a bench or desk*

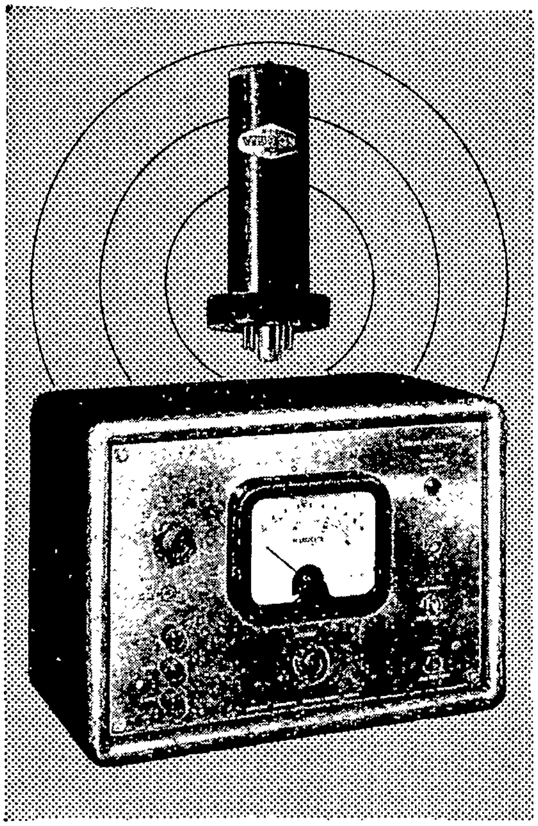
The 'Verifax' Copier is used by laboratories and research organisations throughout the country. It is as near perfect for its purpose—*the accurate copying of a wide variety of documents*—as any copier can be.

KODAK *Verifax* COPIER

Copies single documents up to 8½ × 14 inches, and pages from technical journals and books.



Kodak Limited,
Industrial Sales Division,
Kodak House,
Kingsway, London, W.C.2



E·I·L

The VIBRON

is a new electronic component, which replaces the electrometer valve in the measurement of very small currents.

The VIBRON is a vibrating condenser unit which in a suitable circuit, can measure currents as small as 10^{-16} ampere, or resistances as high of 10^{16} ohms, to an accuracy of ±2% and with a zero stability of ±100 microvolts in twenty-four hours. It can be supplied as a unit for building into instruments of your own design, or, alternatively, VIBRON instruments of several types are available from E.I.L.: the Model 33B Electrometer shown here is an example.

Manufactured under British Patent Nos. 550610 and 774116.

INTERNATIONAL CO-OPERATION IN SCIENTIFIC RESEARCH

THE address in which the Right Hon. R. C. Casey, the Minister for External Affairs and Minister in Charge of the Commonwealth Scientific and Industrial Research Organization, Australia, asked the General Assembly of the United Nations, on September 25, to make more concerted world action to stimulate scientific research for the welfare of mankind a priority task of the Economic and Social Council in 1959 has strong claims on the attention of both scientists and technologists. Mr. Casey was particularly concerned with the time-lag between scientific discoveries and their application to production and human welfare; but he began with a reference to the International Geophysical Year and to the value of the artificial Earth satellites, not only as a spectacular advance in technology but also as a potential source of new scientific data about the regions of space immediately surrounding our planet. Australia has taken full advantage of its special opportunities for research in optical and radio-astronomy which arose from its situation in the southern hemisphere, and her scientists have co-operated actively with scientists in other parts of the world, including the United States and the U.S.S.R. The new giant radio telescope to be built in Australia will be the largest and most far-reaching piece of equipment of its kind in the world.

Some of the possibilities of this new field of knowledge of outer space, involving cosmic rays and the harnessing of these and other phenomena, might as yet be unsuspected, but it is essential that the serious decisions ahead of us in this field should be made by mankind and not just by individual nations. Outer space should be recognized as a field of international concern before it is too late; it cannot be regarded like the high seas, in which outside territorial waters anyone can do what he likes, and which have been the arena of competition for naval supremacy. The world's scientists have met the challenge of outer space, and Mr. Casey urged that it is for the political leaders to meet the challenge it presents in their own field of competence.

While outer space, nuclear energy and electronics are probably the fields in which current scientific and technical advances are the most spectacular and impressive to the ordinary individual, they are, he continued, only part of a much wider revolution in man's position in the universe resulting from research and invention during the past fifty years in practically every field of science and technology. Those fifty years have witnessed developments in the sciences as well as in medicine, agriculture and engineering much greater than in the preceding thousand years. This direct contact with such activities, both in Australia and in many countries of Asia under the Colombo Plan, has greatly impressed Mr. Casey with what has already been achieved by men of science and with the promise of the future. The tide of research and invention is flowing ever more strongly, and it is essential to consider the probable course of scientific development in the next fifty years. For the first time in human history, the whole world might have within its reach the attainment of high standards of material welfare and security.

In a passage reflecting H. A. L. Fisher's well-known reference in his "History of Europe" a generation ago to the abounding miracle of science, Mr. Casey added the qualification "provided we can live together in peace, and concentrate our energies upon the co-operative application of man's advancing knowledge to the control of our physical environment". On this ground he suggested that science must inevitably figure to an increasing extent in the activities of the United Nations and in the Specialized Agencies. There is, indeed, already a very considerable range of scientific activity to be found, for example, in the World Health Organization, the Food and Agriculture Organization, the Technical Assistance Administration, the United Nations Educational, Scientific and Cultural Organization, the International Atomic Energy Agency, the World Meteorological Organization and the Conference on the Peaceful Uses of Atomic Energy. Moreover, the International Geophysical Year is itself a striking and encouraging demonstration of the importance and practicability of international scientific co-operation in the attack on specific problems that call for the combination of several scientific disciplines or techniques.

Nevertheless, Mr. Casey believes that the United Nations could do still more to stimulate and encourage scientific progress and the application of its results, and could play a larger part in planning the strategy of scientific advance, particularly when advance is needed on many fronts and when the world's scientific resources are unevenly distributed. First, he suggested, in regard to research, that it would be useful for the United Nations to look at the total picture to find gaps, to look for promising openings, and to consider the adequacy of the men and facilities available for research that should be undertaken. Next, he suggested, the United Nations could consider the dissemination of scientific knowledge and the results of research, with a view of reducing the excessive lag between scientific discovery and its widespread dissemination and application. Thirdly, he referred to the place of science in education and to the need to recast our ideas as to the proper content of a liberal and humane education.

In this context, Mr. Casey pointed out that the problem of education is much wider than the production of qualified scientists to meet the shortage in particular directions in so many countries. Nor is it enough for educational authorities to add a further subject to the curriculum, to push in a science subject and to take out one of the humanities. He believes that no one is educated who does not know something about science or who knows nothing but science.

Mr. Casey recognizes that all these questions in varying and sometimes overlapping ways fall within the sphere of the United Nations and some of the Specialized Agencies, but he believes that a more concerted approach is needed and that the appropriate body for this is the Economic and Social Council. In view of the relatively little attention given in the past to the idea of a concerted approach to the field of natural science, Australia considers that the Economic and Social Council should give it priority for 1959.

Finally, Mr. Casey suggested that the General Assembly should request the Economic and Social Council to examine the role of the United Nations and the Specialized Agencies in relation to the advance of science and to consider methods of stimulating research in most-needed directions. It should also examine methods of achieving a wider application, dissemination and understanding of new discoveries, taking account of the great inequalities that exist in the scientific resources of different countries.

Apart altogether from the merits of Mr. Casey's particular proposals, his address indicates keen interest in and real understanding of science by the Australian Minister for External Affairs. Moreover, his speech follows a remarkable address on modern science and civilization which the Australian Prime Minister, the Right Hon. R. G. Menzies, delivered to the Australian Medical Congress last March. The trend of thought in both addresses is strikingly similar, particularly in relation to the significance of the Earth satellites, their plea for devotion of the immense resources of science to the service of peaceful human needs and their recognition of the critical importance of a balanced education in which science and the humanities both find a place. Whether or not this is coincidence, it at least suggests that some of Australia's leading political representatives are likely to bring to the consideration of any issues in which scientific or technological considerations are involved genuine awareness of these considerations and a capacity for a balanced judgment.

Mr. Casey did not refer specifically to the discussions of a decade ago on the question of establishing United Nations Research Laboratories, but his recognition that little research could or should be done by the United Nations itself or in the Specialized Agencies, and that the great private and national research foundations and the universities should not be set aside or their work duplicated, suggests that he is fully aware of the practical difficulties and of the criticism those proposals received. Strangely enough, although in the meantime it has become even more apparent in certain fields of research that only co-operative effort will suffice to install and operate economically the expensive equipment necessary, this was not noted by Mr. Casey. The corollary, that no one country can hope to carry out at once all the scientific and technological research that is desirable, quite apart from other essential scientific activities, is the strongest argument for Mr. Casey's thesis, and, whatever its ultimate fate, it should at least contribute to an awareness notably lacking in Great Britain, in the Government and without.

As regards research, Mr. Casey did not advance any fresh arguments. It is, or should be, the function of existing bodies, such as, for example, the Advisory Council for Scientific Policy in Great Britain, to be looking continually for gaps in the front of research, for promising openings, and to assess the adequacy of man-power and facilities available. It is hard to see how it would be any easier on the international plane to find and bring together the men competent for this difficult task. Nor can effect be given to these recommendations without substantial change in the whole political climate and without political representatives of the calibre and outlook of Mr. Casey and Mr. Menzies. Moreover, it is probably still true, as Sir Edward Appleton has pointed out, that the unions organized under the International Council of Scientific Unions are the most useful instruments of international co-operation in science.

A more promising field appears to be in the dissemination of scientific knowledge, for here it is the political factors that have largely been responsible for the major obstacles. They could be removed by fuller understanding, as the success of the Conferences on the Peaceful Uses of Atomic Energy has indicated, but to reduce the time-lag between a scientific discovery and its widespread application can depend on economic and educational factors at least as much as on those that are directly political. There is, undoubtedly, a growing body of experience here that could be pooled, and it might well be that exploration of this proposal of Mr. Casey's could benefit Great Britain directly by bringing home to the Government the importance of certain factors in the dissemination of scientific information and the efficient use of trained man-power which it has been apt to neglect or disregard.

As Mr. Casey himself recognizes, this question is closely related to his third proposal regarding education. On this factor, more than anything else, depends the effectiveness of much of the work already undertaken under the Colombo Plan or through the Technical Assistance Administration to assist in scientific and technical developments throughout the world. If we can solve the problem of education on the lines he indicates, we shall have gone far to ensure the more efficient use of our existing resources in science and technology, quite apart from making it easier to expand that effort. Moreover, it is on the basis of such an educational policy that we can best hope to see the international co-operation that is undoubtedly required in the attack on some of the problems with which the widening horizons of science confront us, and the sustained support that the successful execution of an agreed programme demands. It should not be forgotten that it is one thing for the appropriate programme or project to be agreed and another for the resources to be allocated for its initiation. Even on a national scale, that is not very easy, and it is unlikely to be easier on the international plane. No less important, however, is the continuing support of the project until it is complete. The difficulty which international organizations have hitherto experienced in securing such support from year to year warrants little optimism that, without considerable raising of the standards of education, integrity and objectivity in political circles at all levels, we can hope for the co-operation and sustained support required for an attack on any major scientific or technological objective on the scale necessary in the modern world. Mr. Casey's proposals may, however, lead to a clearer understanding of what is possible if the individual nations are willing to pay the price ; and they remind the scientist and technologist once more that he has responsibilities in this matter of education which are not simply professional but those of the citizen, too.

LIFE OF HENRY ARMSTRONG

Henry Edward Armstrong, 1848–1937

The Doyen of British Chemists and Pioneer of Technical Education. By Dr. J. Vargas Eyre. Pp. xix+325+15 plates. (London : Butterworths Scientific Publications, 1958.) 30*s*.

THIS biography of H. E. Armstrong by one of his former pupils, Dr. Vargas Eyre, details the life of a vivid personality spanning the remarkably eventful years from 1848 to 1937. He began the study of chemistry at the Royal College of Chemistry just before Hofmann left to return to Berlin. Edward Frankland succeeded to Hofmann's chair in 1865 when the idea of chemical valency was emerging and before Kekulé's benzene formula was generally known. But before Armstrong left the stage, valency had received an explanation in terms of the electron, and the three-dimensional structures of such complex compounds as the sterols had been elucidated. Truly a remarkable advance in a single life-time, and the recent synthesis of the diamond in a tetrahedral anvil at pressures of 100,000 atmospheres and temperatures near 2,000° C. shows that the forward march continues.

In 1865 public sewers were almost unknown, and water pollution rampant. Frankland was one of those charged to tackle the problem and he set 'H. E.' to devise a method for estimating the pollution. During this period he attended lectures on geology by Ramsay, on physics by Tyndall and those on the place of science in education by Huxley. Later, Frankland urged him to go to Leipzig to work with Kolbe, and he did so in 1867 and remained nearly two and a half years working for his doctorate. On his first day in Leipzig, Kolbe suggested that Armstrong should examine the mixture formed on sulphonating phenol. Kolbe was also a forceful exponent of both attack and defence on chemical questions, and all the guiding principles in Armstrong's subsequent career had thus been fixed before he was twenty years old : purity of food and especially of milk and beer with the great problems of agriculture and health (Frankland), an abiding interest in geology (Ramsay), the life-long crusade on the teaching of science and its importance to industry (Huxley), the dominating role of sulphonation in his research work and the whole crowned by a dynamic character and a powerful debater (Kolbe). Apparently such characters no longer emerge from the mould in this plastic age.

On returning from Germany 'H. E.' started his teaching career at St. Bartholomew's Hospital and continued in this part-time post for twelve years. It is said he never received more than £50 a year for the work. Already in 1875 he was junior secretary of the Chemical Society, and when the senior W. H. Perkin retired he activated and came to dominate the Society after 1880. He was one of the first four professors appointed to the new City and Guilds Central College in 1884, and his research output began to mount. Many papers appeared on the sulphonation of naphthalene, others were on the terpenes, and particularly camphor. In 1888 he advanced the quinone theory to account for the colour of organic compounds, and both with pen and in debate he vigorously championed the role of water in electrolysis.

Possibly his many wide interests prevented him from making any great advances in the laboratory, but great credit is due to his school for producing chemists such as F. S. Kipping, A. Lapworth, T. M. Lowry, W. J. Pope, and W. P. Wynne among others. His forward vision embraced the importance of crystallography in chemistry and led him to appoint Henry Miers to lecture to his students on the subject.

The lack of suitable posts for chemists in industry at that time was reflected in the fact that he never had more than about a dozen senior students, and this probably influenced the authorities to close his chemistry department in 1911. After nearly thirty years of great service to the Central College he was given notice to quit without pension.

Armstrong was a fiery crusader who occupied the centre of the stage in many causes, but his advocacy of the teaching of science in schools also showed considerable statesmanship, as witness the paper he presented on the subject to the British Association in 1889 and its sequel in the successful trials of the heuristic method at St. Dunstan's College and Christ's Hospital. It is not too much to say that his work for education profoundly influenced science teaching in all English-speaking countries. It gives much food for thought that in spite of the urge for technical education and the application of science to industry in the fourth quarter of last century, these very problems are a matter of life and death to us in the third quarter of this century.

Dr. Eyre's account of Armstrong's life has clearly been a labour of love, and in the interest of the history of science it is well that it has been made. Perhaps it is rather long even for such an eventful life, and if much of the minor matter had been sacrificed Armstrong's great record of service to science and education would have shone all the clearer.

G. R. CLEMO

FRAUDULENT DOCUMENTS

Suspect Documents

Their Scientific Examination. By Dr. Wilson R. Harrison. Pp. viii+583. (London : Sweet and Maxwell, Ltd., 1958.) 84*s*. net.

THE book under review is a very important contribution to the published knowledge on the examination of suspect documents, particularly as it is the first complete review of the opinions of an acknowledged British expert on the subject.

Fraudulent documents have existed as long as genuine documents, and the problem of their detection has been of considerable importance to States and individuals. This problem existed before science was sufficiently advanced to assist in its solution and, therefore, there grew up a tradition of examination of documents based on superstitious credulity and with no scientific background whatsoever. It is against this tradition that the modern scientific document examiner has to fight constantly in courts of law and in public opinion. A. S. Osborn in the United States was the first to show successfully the necessity for the recognition of scientific principles in this sphere, and his "Questioned Documents", first published in 1910, is the classic on the subject. Other books of his, such as "The Mind of the Juror", indicate the difficulty experienced by the document examiner in divorcing the mind of the layman from preconceived ideas and directing it to the scientific facts which are demonstrably present in the examiner's report. In the 1920's and early 1930's, C. A. Mitchell in Great Britain most actively pursued and reported the search for scientific methods of examining documents, and a number of other authors have written on various aspects of document work; but little has been reported on the comparison of handwriting and typewriting, although considerable advances have been made. While Ordway Hilton in 1956 described American experience, the volume under review fills the gap from the British point of view, which has been created for a modern evaluation of existing techniques, and the book must therefore be read by all who are interested in these matters.

The book may be divided into four parts. First, the scientific examination of documents for alteration or fraud. This includes modern techniques such as, for example, the chromatography of inks. Secondly, the photographic techniques used in documentary analysis for various purposes are discussed, with the difficulties arising in making photographs for record purposes, and also the manifold special techniques required to detect alteration, erasure, obliteration, indentation, mutilation and all the other ways of ill-treating documents. Thirdly, handwriting and typewriting comparisons; these are extremely fully and authoritatively dealt with. Fourthly, the many requirements for obtaining the maximum use in court of handwriting and typewriting evidence are given, commencing with advice to the police in securing the best available material and ending with advice to counsel on the special problems arising in the presentation of handwriting evidence.

Each section is exhaustively and comprehensively treated and contains a mine of information for those wishing to understand the principles and methods involved.

There is some repetition, admitted frankly by the author, much of which is necessary both to ensure the completeness of each individual section and also to emphasize salient points. Nevertheless, I found that the repetition in Chapters 8–15 on handwriting and typewriting comparison, which the author undoubtedly has nearest to his heart, detracts from the enjoyment in reading the chapters.

The book is beautifully and carefully produced, and the illustrations are clear and informative. Only four minor proof-reading errors were detected, which is very few considering the size of the book. The index is comprehensive, and a glossary is included; this appears to be neither necessary nor helpful to the public for which the book is written. L. C. NICKOLLS

THE LAND OF AUSTRALIA

Land Utilization in Australia

By Wadham and Wood. Third edition by Sir Samuel Wadham, R. Kent Wilson and Joyce Wood. Pp. xxii + 344 + 77 plates. (Melbourne: Melbourne University Press; London: Cambridge University Press, 1957). 40*s*. net.

THE first edition of this book, by Prof. Wadham and the late Gordon L. Wood, then lecturer in economic geography in the University of Melbourne, was completed in 1938 and published in 1939. The second edition, completed in December 1947, appeared in 1950, so that the three editions mark approximately ten-year intervals. In the meantime, the book has become an indispensable standard work. The story is now brought up to date partly with the help of Kent Wilson, who is lecturer in economic geography in the University of Melbourne. The senior author has become emeritus professor, and been knighted; Gordon Wood's daughter contributes a valuable new series of maps and diagrams.

These decades have witnessed some remarkable, sometimes curious, changes in land use in the continent. The early White settler had found the land of Australia more nearly virgin than any territory on Earth, for the aborigines, never numerous, neither tilled the soil nor kept herds of animals. They lived frugally by hunting and gathering edible fruits and roots with a minimum effect on the flora and fauna. If their presence resulted in occasional bush fires it is likely that at least as many fires were caused by lightning or other natural causes. At the same time the isolation of the continent had led to a balance between a peculiar flora and a peculiar fauna different from that anywhere else in the world. The physical environment of relief, climate and soil is repeated elsewhere, but the biotic environment is unique. It presented, and continues to present, difficult and challenging conditions to the spread of Western methods of both arable and pastoral farming. The decades preceding the uniting of the States as the Commonwealth of Australia in 1901 were characterized by a vast extension of cultivated acreage and of flocks and herds, and by a spirit of ebullient optimism. This optimism was part of the process of nation-building exemplified by the publication of such works as "Australia Unlimited". Lone voices, such as that of Prof. Griffith Taylor, in the nineteen-twenties, which dared to suggest there existed a dead heart of desert which could not be revived, were howled down. To-day the difficulties are realized: the strength and importance of physical factors, above all availability of water, are fully recognized.

The authors survey the historical sequence of settlement—wool, then wheat, then dairying, then irrigation agriculture, with each in turn coming to occupy a definite but by no means fixed position in the whole. The present position is that the total of cropland, including sown pastures and orchards, is only 2·5 per cent of Australia's 3,000,000 square miles. Although 55·8 per cent is claimed as natural pasture and rough grazing, much has a very low carrying capacity. The depression of the 'thirties had reduced the initiative and morale of the countryside, the varying phases of war demanded adaptations of farming which were quite impossible. At first Britain wanted all the wool, but no shipping was available for fruit and wine and little for wheat.

Then Britain, as Danish and other supplies were cut off, demanded vast quantities of dairy produce and bacon. The arrival of a million Americans resulted in an insatiable demand for orange juice and milk. The post-war period has seen its violent changes too—the 1951 inflationary demand for wool, and then the collapse of prices in 1952. Despite the vast reserves of land the present trend is rural depopulation, and the stupendous growth of Australian cities. Mechanization, with consequent reduction of labour force, and intensive development of the more favoured lands are characteristic of the present: the future may hold many surprises. L. DUDLEY STAMP

THE PAREXIC ANALYST

Applied Analysis

By Prof. Cornelius Lanczos. (Prentice-Hall Mathematics Series.) Pp. xx+539. (London: Sir Isaac Pitman and Sons, Ltd., 1957.) 55*s.* net.

APPLIED analysis—Prof. C. Lanczos suggests the adjective 'parexic'- -is described by him as "the analysis and design of finite processes which approximate the solution of an analytical problem". The 'pure' analyst is, say, concerned with the existence of approximations to arbitrary functions by special types of functions, such as polynomials, to within an arbitrary ε, the 'numerical' analyst wishes to calculate the polynomial in some specific case, for an assigned numerical ε: the 'parexic' analyst is more interested in construction, and economy of construction, minimization and estimation of error, than in existence or calculation. Such a classification can scarcely be clear-cut; and the problems of the parexic analyst must in any event be modified by the invention of new computing devices, but a label for those interested as much in the theory as in the processes of numerical analysis may be useful. In some respects, the aims of the book resemble those of Householder's "Principles of Numerical Analysis", but Prof. Lanczos deploys on a broader front, in less detail and in a more discursive style. A sound knowledge of calculus and some acquaintance with the complex variable and Cauchy's theorem will will enable the student to read the book with ease.

The chapter subjects give a good indication of the main content, though not of the richness of the material: algebraic equations; matrices and eigenvalues; large-scale linear systems; harmonic analysis; data analysis; quadrature methods; power expansions. From a book full of interest, a selection of special items, even if depending on personal preference, may be worth making. Bernoulli's method is prominent in the chapter on algebraic equations, and complex roots, so important in stability criteria, receive much attention. The geometrical interpretation of matrices and eigenvalues, to illustrate their algebraic treatment, should greatly help the novice. The 'spectroscopic' method, which eases the calculation of small eigenvalues, is particularly dear to the author, since it allows him to exploit his favourites among the orthogonal polynomials, those of Chebyshev; indeed, these keep turning up aptly throughout the book in quite surprising places. The study of the inversion of the Laplace transform is most valuable, in the light of recent technical requirements, and Chebyshev plays a part. Numerical integration is centred on Gaussian methods, with a modification designed to avoid the troublesome evaluations at irrational points without serious loss of accuracy; the author ignores Chebyshev in this connexion, though his rules are, I believe, still much employed by naval architects. In expansion problems, the construction of expansions which shall furnish reasonably good approximations over a whole range, rather than very good at one end and poor at the other, is helped by using orthogonal polynomials, and here, as also in the related problem of speeding up convergence, the Chebyshev polynomials are again prominent, Finally, introductory historical paragraphs to each chapter help in setting the scene and preparing the reader for what is to follow. CHROMOSOMES

Looking at Chromosomes

By John McLeish and Brian Snoad. Pp. vii+88 (48 plates). (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1958.) 16*s.* net.

THE quality of a book of photographs must rest not on the technical standard of the photographs, for this is taken for granted, but on the suitability of the subject and on the discrimination and skill of arrangement. Chromosomes are certainly photogenic, but can their cyclical changes in shapes and movement be captured in a series of post-mortem stills? In trying to find an answer it is difficult not to make the unfair comparison with the enthralling films of live chromosomes that show every movement, relevant and irrelevant, in a most dramatic way.

The photographs in "Looking at Chromosomes" are so well chosen and arranged that they show the changes in shape and most of the relevant movements of the chromosomes. They cannot show the movement of chromosome arms or the unorderly jostling of the paired chromosomes for their place on the metaphase plate of meiosis which have been revealed in moving films. But the essentials for interpreting chromosome form and movement and their significance in heredity are clearly shown. The unique feature about the series is that the cyclical changes in mitosis in roots, in meiosis in the male pollen mother cells and female mother cells are all taken from one organism—the regal lily. This is no mean achievement, for most organisms have an obscure part of the chromosome cycle which is technically difficult to show. The short text of explanation emphasizes the genetic implication of the chromosomes. Two minor criticisms may be made here. The cytoplasm is described as "a highly viscous fluid". This is only true sometimes; often the cytoplasm is little thicker than water. The constancy of the complement of chromosomes is not so universal in differentiated cells as the over-simplified statement in the last chapter implies.

The addition of a simple time-scale of the chromosome cycles would add greatly to the completeness of the general picture.

For those who do not have a moving film of chromosomes or a projector, "Looking at Chromosomes" is quite the best and only complete account in photographs of our heritage—the chromosomes.

D. LEWIS

ELECTRON MICROSCOPY IN BIOLOGY

By PROF. R. D. PRESTON, F.R.S.
Department of Botany, University of Leeds

INVESTIGATION of biological structures smaller in dimension than the resolution of the light microscope has until comparatively recently been confined to a relatively few laboratories throughout the world. This was because the physical principles involved were such as to be unfamiliar to the majority of biologists and because the equipment required was normally not found in their laboratories. Apart from the replacement of visible light by ultra-violet light in the conventional type of light microscope (increasing the resolving power by a factor of about 2) the methods used were those of polarization microscopy and X-ray diffraction analysis. With neither of these two methods was it possible to produce directly a visual image of the structures being investigated; a complex mental process intervened between the observations made and the structure delineated. The methods suffered, moreover, from other serious drawbacks. Only structures which were crystalline could be investigated, that is to say, substances with atoms and molecules arranged in a regularly repeated order in space. The smallest objects which could be studied were microscopic in size, and the observations made upon them frequently enabled only an 'average' structure over the whole specimen thickness to be determined. Again, whereas in the light microscope the smallest dimension directly observable is of the order of 1000 A., the power of X-ray diffraction analysis lies in the dimension-range of a few angstroms, and even the method of low-angle scattering enables the form of an object to be calculated only up to a dimension of a few hundreds of angstrom units. This left a wide gap of structure completely outside the scope of investigation.

In electron microscopy, biologists have been presented with a tool which, while not free of its own drawbacks, and not in any sense replacing the older methods, has removed some of the particular disadvantages inherent in these methods. Moreover, the preparative techniques and the observational methods are basically those of light microscopy, in which biologists already excel. This newer technique has therefore thrown the field of submicroscopic structure open to biologists, and the opportunity thus given has been taken up vigorously by biological departments throughout the world. This constitutes a revolution in histology perhaps of equal rank to that heralded by the development of the compound light microscope during the past century. The meeting held recently by the Linnean Society on applications of electron microscopy to biology, the first meeting in Britain confined solely to biological applications, demonstrates clearly the rapid progress which has already been made in this field, so rich in promise.

The use of this comparatively new instrument is not without its dangers, and these fall especially heavily upon the biologists. The specimen to be observed must be sufficiently thin to be penetrated by the electron beam. At best, therefore, the specimen thickness can be no more than 0·1μ and preferably, for high resolution, not more than 100–200 A. It is observed in a high vacuum, and is therefore completely desiccated, and the absorption of electrons causes a considerable rise in temperature. With biological material particularly, therefore, the investigator must at every stage, both in preparing the specimen and during observation, be prepared for the development of artefacts. At all stages and with all specimens it is highly desirable that results of electron microscopy should, in the first instance, be checked against observations with the older and more familiar techniques.

Observations in the electron microscope can be interpreted with the least ambiguity with specimens of robust material the structure of which is already fairly well known. Such a material is the plant cell wall. Some cell walls lend themselves to preparation for observation by relatively mild mechanical treatment, and the wall of *Valonia* vesicles is particularly convenient. This was historically the first organism yielding an electron micrograph of relatively untreated cell wall material[1]. There rapidly followed a succession of publications[2] on other wall material usually prepared by grinding in a blender. It soon became clear that the first observation, that the cellulose consists of long narrow threads (in *Valonia* of the order of 200 A. in diameter), is of universal application in the plant kingdom (Fig. 1). This harmonized completely with the already known structure of cellulose in the form of long molecular chains of β1–4 linked glucose residues lying, sometimes more, sometimes less, parallel to each other. With *Valonia*, in particular, these long threads—termed 'microfibrils'—were found to be arranged parallel to each other with sufficient accuracy and to be sufficiently crystalline to give an electron diffraction diagram in the electron microscope (Fig. 2). This diagram fully confirmed that the microfibrils consist in the main of long molecular chains of glucose residues lying parallel to each other and in large part spaced in a regular crystalline space-lattice. This combination of electron microscopy with electron diffraction analysis of identically the same specimen observed in the electron microscope offers the biologist a most powerful tool in the study of material to which these methods can be applied. Not only can a visual image be recorded but the molecular structure of the material can also be determined, a combination which has already led to some most spectacular results[3], including the demonstration of the clear necessity for a re-determination of the unit cell of cellulose derived by the method of X-ray analysis.

The more recent use of ultra-thin sectioning and of surface replication[4] has served largely to confirm structures already revealed for a wide variety of cell walls by the older methods of polarization microscopy and X-ray diffraction analysis[5]. Moreover, the visual delineation of structure in minute pieces of material which electron microscopy allows has enabled considerable advances to be made in the question of the synthesis of cell wall materials. Thus, it has been

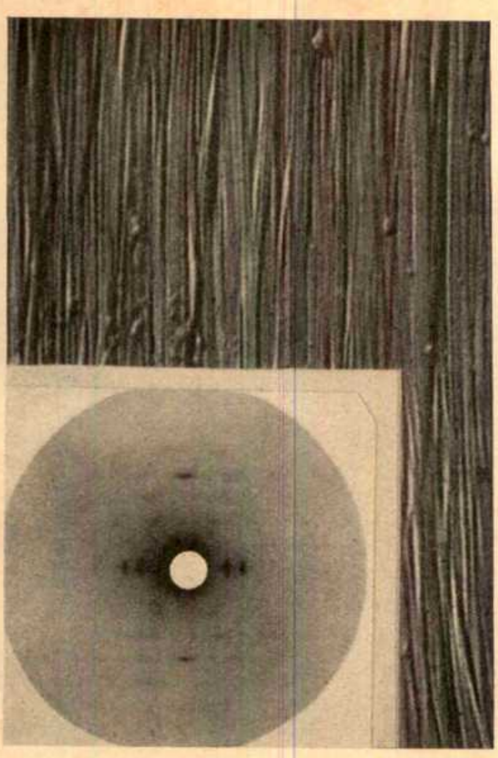

Fig. 1. Electron micrograph of a single lamella of the wall of the vesicle of *Valonia ventricosa*, palladium–gold shadowed (× 40,000) Note the parallel microfibrils occasionally twisted

Fig. 2 (inset). Electron diffraction pattern of a lamella similar to that shown in Fig. 1, but unshadowed, and in correct orientation with respect to Fig. 1. Note the line of arcs along the equator (parallel to the shorter edge of the page) perpendicular to the length of the microfibrils in Fig. 1

reported[6] that, whenever a wall lamella is observed which is just being laid down by the cytoplasm, the wall surface is covered by a series of aggregations of corpuscular bodies from which cellulose microfibrils appear to diverge. The observation of the first formed wall around swarmers has already produced results of outstanding importance from this point of view[7], and present and future work on this material is of the greatest promise. Again, once more in harmony with the older work, it has turned out that the microfibrils in the walls of growing cells are arranged more or less transversely to cell-length, particularly in the innermost wall lamellæ abutting upon the cytoplasm. It is claimed that the outermost layers of such cells, away from the cytoplasm, are constituted of microfibrils which are more nearly randomly or even axially oriented. On the grounds of these electron microscopical observations, Roelofsen[8] has proposed a hypothesis to explain the relationship between the expansion in area of the cell walls of growing cells with the growth of the cell. On this hypothesis, in a freely growing cell, the microfibrils are first laid down by the cytoplasm more or less transversely to cell-length and, as the cell elongates, this lamella, moving outwards through the wall as newer lamellæ are laid inside it, becomes elongated through the agency of turgor forces so that the microfibrils become progressively oriented more and more away from the transverse. While such a mechanical explanation of the reaction of the wall to growth processes has not met with universal acceptance, and while the hypothesis makes no attempt either to explain how the microfibrils come to be arranged transversely or how it is that cells elongate rather than increase uniformly in dimensions, it does include principles which cannot be ignored in discussions of the growth process.

Considerable attention has been paid to the construction of plasmodesmata in primary walls and pits in secondary walls[9]. It has become clear that plasmodesmata are indeed penetrations of the wall by cytoplasm which runs among rather loosely packed microfibrils, and that the membrane of bordered pits consists of a loosely woven network carrying the central torus when a torus occurs. Along more or less the same lines, it has similarly been shown by observation of ultra-thin sections that the pores in sieve plates of *Cucurbita*[10] and of other species[11] are completely filled with cytoplasm, a simple observation which seems to rule out all existing theories of phloem transport except those involving the use of metabolic energy.

Among those whole organisms which can readily and simply be observed in the electron microscope, the viruses and the bacteria are, of course, outstanding. The beautiful electron micrographs of Wyckoff and others have shown how readily the shape and size of virus particles can be demonstrated[12] as well as the beautifully regular way in which these particles become associated to form crystals[13]. The bacteria have been examined both whole and in ultra-thin section[14] so that these minute organisms are now open to critical examination.

It is, however, perhaps in the cytoplasmic organization both of plants and of animals that electron microscopy, and especially the observation of ultra-thin sections, reaches greatest power. Here structures are being revealed which were not known before the development of electron microscopy, and it is therefore in this field that artefacts have most carefully to be excluded. It is impossible in this short space to mention even briefly all the important observations which have already been made in this field, and the choice of illustrative material here is therefore quite arbitrary. Considerable attention has been paid to those elongated organs known as flagella which by movements of various kind propel motile cells through the substrate. Whereas with motile bacteria[15] the flagella appear to be simple fibrils, all flagella so far investigated in higher plants and animals[16] appear to be multiple and to contain eleven separable strands (Fig. 3). Ultra-thin transverse sections of these flagella have shown that these eleven strands are arranged in a specific manner, two central strands being surrounded by nine others arranged more or less in a cylinder. In the spermatozoids and other motile cells of some plants the flagella are clothed with a mat of fine fibrils—to which the German name 'flimmer' is applied—and occasionally with spines and hooks in an intriguing array. These observations are even at present of considerable taxonomic importance and may well pave the way for an understanding of motility in these motile cells. Current research is aimed at tracing the connexion between the bases of these fibrils and the internal organelles of the parent cells.

The cytoplasm itself has provided a wealth of structural detail (Fig. 4) and the larger granular inclusions have naturally been the first to demand attention. Within chloroplasts, for example, it has been confirmed that the chlorophyll lies in the so-called 'grana' and that both the grana and the ground substance are laminated. High-resolution microscopy has further demonstrated that these

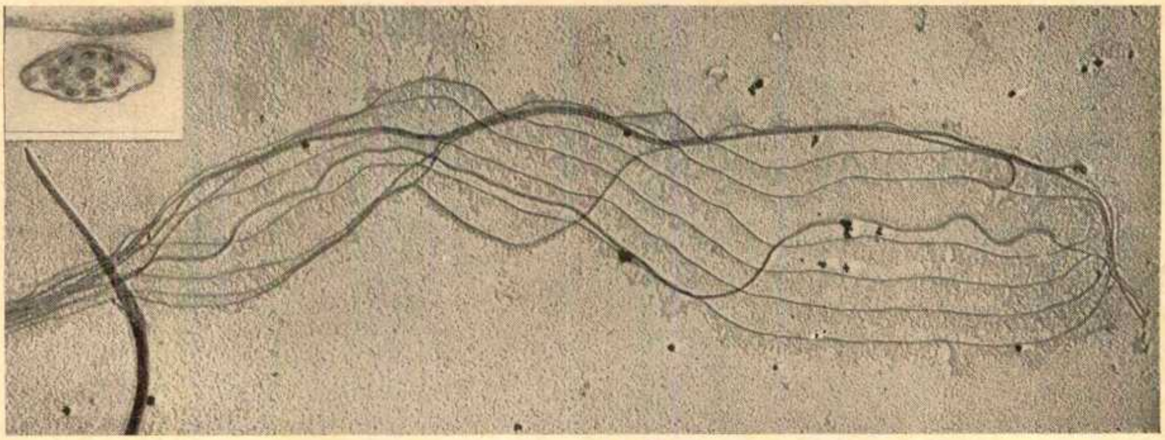

Fig. 3. Electron micrograph of an intact and dismembered flagellum of a *Sphagnum* spermatozoid (× 5,500). (Manton and Clarke, 1952) Inset: Electron micrograph of a transverse section of a flagellum of a *Sphagnum* spermatozoid (× 38,000). (Manton, 1957.) (Photographs prepared by B. Clarke)

lamellæ are often double and folded in complex ways[17]. This again confirms the opinion often expressed, based upon the physiological observations of the absorption spectra and fluorescence spectra of chlorophyll in solution in the leaf and as a sol. Mitochondria have similarly been shown to possess a membrane from which peg-like protrusions stand out towards the inside of the granule[18]. These protrusions have been shown in several instances to be double and may be infoldings of a membrane. The question of the presence of a membrane around the nucleus in the resting phase has been answered once and for all. Both in plants and animals the nucleus has a clearly marked membrane which is double and which is perforated at frequent intervals[19]. Little definitive evidence has yet been presented in electron micrographs concerning the structure of chromosomes.

The structure of the cytoplasm surrounding the more obvious granular inclusions has proved to be more complex than speculations, based on observations under the light microscope and the physical properties of the material, had led us to expect. It is undoubtedly in this field that the greatest care has to be taken in preparing the specimen in order to prevent the development of artefacts. The general appearance of the more organized cytoplasts is that of a series of vacuoles limited by fine membranes of the order of 100 A. or less in thickness which are probably double. This reticulated appearance gives the impression that the cavities lying between the membranes are empty. It must, however, be realized that the complicated imbedding technique, including the imbibition of methacrylate monomers, may cause solution of cytoplasmic constituents and therefore their disappearance from sections. It should be realized, too, that the *p*H of the fixing fluid is highly critical and that the only criterion at the moment for the suitability of any particular fixation method lies in the clarity of the resulting electron micrograph. More complicated regions such as the Golgi apparatus[20] have clearly been identified and the structure worked out. The widespread appearance has been noted of a well-marked reticulate system consisting either of vesicles or long narrow canals or tubes or plates bounded by double membranes, named by Porter and Kallman the 'endoplasmic reticulum'[21], provisionally interpreted as being associated with conduction or circulation of various substances.

Electron microscopy has thus made it clear that one common theme seems to run through the structure of the whole of the cytoplasm and its inclusions, namely, that the structure is based on a lamellated system, and it seems that biochemical activity is specifically associated with lamellæ. This is, of course, entirely in harmony with the generally accepted view, based on physiological evidence, that metabolic processes occurring in cells are associated at some stage with an adsorption phenomenon at surfaces.

In addition to this direct attack on biological problems by the method of electron microscopy, it must not be forgotten that the electron microscope is playing a great part in an indirect way, too, in the

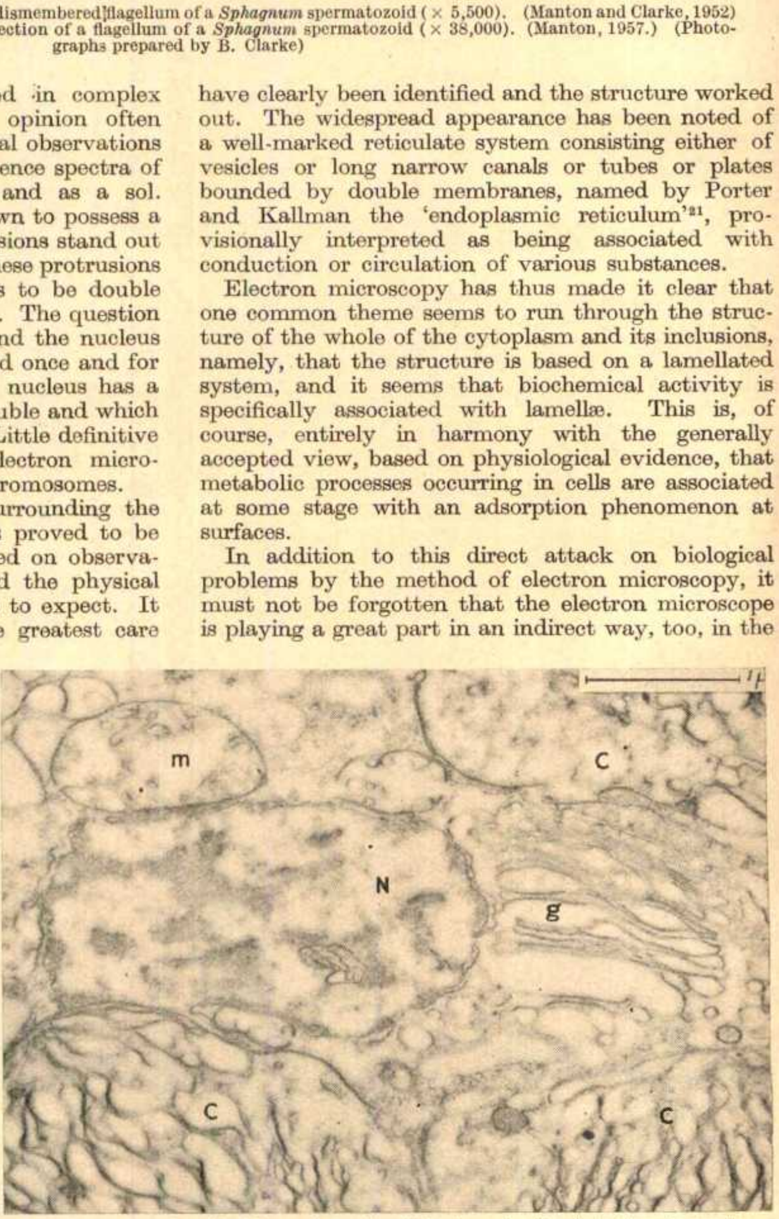

Fig. 4. Section of a cell of *Chrysochromulina chiton* (a marine flagellate) showing nucleus (*N*), parts of three chromatophores (*C*), mitrochondrion (*m*), a Golgi area (*g*), etc. Unshadowed (× 22,500). (Parke, Manton and Clarke, 1958. Photograph prepared by B. Clarke)

development of the biological sciences. Thus, the localization of ribonucleic acid or of enzymes and enzyme systems on cytoplasmic particles of submicroscopic dimensions[22] could not have been achieved without the simultaneous electron microscopical observation of the particles and the verification that the material under investigation contained no other bodies. Again, in the chemical fractionation of biological material the results are on a much surer foundation now that it is possible to check the purity of the extracts by electron microscopy. One case in point refers to the extraction of plant cell wall material[23] in which the extraction was watched under the electron microscope at each stage, so that not only could the chemical composition of the material be given but also the site from which the various components had come could be located with some precision.

CONSERVATION OF NATURAL RESOURCES

THE International Union for the Conservation of Nature and Natural Resources held its sixth General Assembly (and seventh Technical Meeting) in Athens during September 10–19, under the presidency of Prof. R. Heim of Paris. The main theme of the technical discussions was that of soil and water conservation, one so wide that it was necessary to subdivide the papers submitted (by delegates from more than thirty countries) into groups dealing with the technical aspects of evaporation and run-off, the use of vegetation in the control of erosion, the effects of dams on habitat and landscape, and the development of aquatic resources, as well as the ecological solutions of specific water and soil conservation problems. In a special address to the assembly, Dr. R. Scott Russell gave a thoughtful and interesting analysis of the problems set by the influence of atomic radiations and wastes on the vegetation cover.

The rapid development of ideas of water control was well illustrated by attempts to see in evaporation from land surfaces with different types of vegetation cover, variants in the eddy-diffusion systems which might exert comparatively little influence on the over-all evaporation-rates of a considerable tract of country. Much attention was directed to the influence of the vegetation or other cover on the soil temperature and indeed to the energy relations of the evaporating surfaces, and the physical conditions which determined how rapidly water ran off or sank out of reach in the soil. H. C. Perriera, in particular, showed the importance of studying 'rainfall acceptance' and the conditions governing the structure of soils in this connexion. W. Robyns thought that in tropical regions the role of a permanent vegetation cover in maintaining the hydrological equilibrium was of the first importance because of its influence on the temperatures and structures of soils, and on biologically induced fertility. Thus, although several lysimeter studies from various parts of the world were reported, the results from them were generally regarded as open to various interpretations, giving little final assistance in solving the physical problems of semi-arid soils.

Considerable attention was also devoted to the use of dams to impound water for irrigation or for general industry. The losses of water occasioned by different sizes of dam and diverse types of dam distribution were compared with those from other forms of utilization, with some tendency to conclude that water was best used where it fell, particularly in regions requiring protection from desiccation or soil erosion. The value of fish culture in impounded waters as a source of protein food was regarded by some speakers as a compensation for any water losses.

It was made extremely clear that conservation of water is of the first importance in most countries, particularly in the highly industrialized and the arid, and that the problems involved in wise planning and utilization are rarely those for the engineer alone but are likely to involve not only the physicist and pedologist but also the meteorologist, plant physiologist and ecologist, often in conjunction with forester and agriculturist.

Much attention was naturally directed to problems in the Middle East, North Africa and the Mediterranean region generally. Several speakers adopted a historical approach to conservation of water and erosion of soil, very appropriate against the background of ancient Greece. They saw in deforestation and in wasteful and ignorant methods of land use the reasons for the decline of Mediterranean civilizations, the lessening of cultivable land and the spread of semi-desert conditions in this region. The arguments developed and evidence produced were in marked contrast to the well-known views of Huntingdon and others which base changes of this type on a supposition of climatic desiccation. G. V. Jacks threw still another idea into the arena, the conception that a society's socio-economic status determines whether it is 'fertility-destroying' or 'fertility-creating'. "Thus the capacity of the world for food production is limited not by land or soil-fertility but by the productive capacity of its urban industries," which will be balanced by an equivalent energy in agricultural development. "A wealthy city will create a productive soil," and the relative scarcity of large cities in the Mediterranean might thus imply low productivity.

The technical papers almost always led to general discussions involving the world background of rapidly increasing populations and the over-riding problem of how to marry the need for increased production with the preservation of natural resources, either as a long-term economic need or for scientific or amenity aims. As this assembly showed, the Union is becoming a meeting-ground between those whose aims lie chiefly in production and those who are mainly interested in the protection of Nature and natural resources. Edward Graham remarked that those who emphasize the need for protection or for production are respectively contrasting, on one hand, the necessity for the maintenance of the stability of natural environments and their organic life and, on the other hand, the manipulation of habitats in order to obtain the organic products required. It is becoming evident that these rival aims are nearer than is often thought, for the 'marginal' or more extreme habitats need protection if they are to be at all productive, and, in contrast, high production can only be based on those habitats which are able to withstand manipulation, that is, are ecologically so 'buffered' as to permit a considerable latitude in treatment. Conservation, therefore, consists essentially in the identification and classification of environments followed by the development of protective and stabilizing forms of production for ecological systems which are unstable. A paper by forestry representatives of the Food and Agriculture Organization was of interest in this connexion, because it described how, in scrubby protection forests in semi-arid regions, the use of branches and small timber for the production of charcoal in specially devised kilns had made it possible to maintain the necessary permanent vegetation cover and yet produce a necessary fuel for the inhabitants.

The multiplicity of considerations involved in conservation often makes it difficult to popularize the basic conceptions. While it is evidently the role of scientists, on one hand, and of government, on the other, to deal with multiplicity of factors and of aims and with their integration, conservation and the "real future of all natural resources (again to quote Edward Graham) lies in the hands of the peoples themselves, for it is they who till the fields, graze the flocks and cut the forests. If the people are to care for the land they must have a stake in it. For this reason, ownership of the land, or at least a share in the proceeds of its production, becomes important".

If the science and technology of the management of resources are to be brought within the people's reach, local organizations are required not only to unify the efforts of the local community but also to utilize, in full, the technical assistance which may be made available from government. Only by such means can the work done become part of the pattern of living and culture of the community. The role of education is equally important, and both these aspects of the problem were considered to be particularly urgent in under-developed countries, where the uncontrolled growth of populations is likely to lead to over-exploitation and to the irreversible destruction of natural assets and amenities. Education in such societies will involve not merely the spread of technical information but also the need for the indigenous inhabitants to acquire a feeling of responsibility for the resources of their land and its wild life. This must be coupled with the presentation of necessary ideas on conservation both to industrialists who may seek to exploit present conditions at the expense of the future and to administrators who must acquire a long-term outlook with a capacity to supply leadership in balancing immediate demands for exploitation against the need for preserving the natural heritage for the future. In discussing the measures which might be adopted to bring about these threefold aspects of education, the assembly concluded.

W. H. PEARSALL

ADVANCES IN THE USE OF RADIOISOTOPES

Medical Uses

THE developments which have occurred in the use of radioisotopes in medicine, as doubtless in other departments of science, have usually been associated with technical developments on other lines also. The availability of radioisotopes as a tool stimulates the imagination and ingenuity of those using it. This has been reflected in the past in counter techniques ; but the development of chromatography, scintillation mapping, methods of section-cutting, autoradiography and other techniques are all reflected in the papers submitted to the second International Conference on the Peaceful Uses of Atomic Energy.

In biochemical work one of the most important developments has been the use of tritium, which, by virtue of its soft beta-radiation, permits the localization of uptake of a labelled compound, thymidine, within 1μ of the structure taking it up, so that accurate information is obtained on chromosome duplication and the timing of synthesis of deoxyribonucleic acid, nucleolar synthesis of deoxyribonucleic acid and cell migration from crypts to villi in the intestinal epithelium (*P*/842). The necessity for correction for the absorption in protoplasm and the effects of nuclear flattening was stressed in another paper (*P*/323), since these factors must influence the effect on the photographic emulsion. Only metabolic reactions can detach the tritium from the labelled thymidine, but tritium in high concentration may give large doses of radiation locally as well as having different metabolism from hydrogen.

Much of the Russian work on animals has focused attention on the central nervous system, and in this respect they have shown (*P*/219) that methionine-^{35}S is an essential amino-acid for the cells of the brain and is synthesized into protein. An interesting investigation of protein synthesis (*P*/846) demonstrated the relatively sudden synthesis in 6·5 min. of the ferritin molecule by using valine-^{14}C. It is emphasized that it occurs directly from amino-acids and not from polypeptides or larger molecules. A relatively comprehensive review of protein metabolism determined by radioisotope methods was given (*P*/77). The investigation of detailed metabolic processes was exemplified by the demonstration of the citric acid cycle in yeast using carbon-14 dioxide (*P*/1563), the relationship of phosphoryl choline, phosphoryl ethanoline and phosphoryl serine into phospholipids in the central nervous system (*P*/2318) and the use of phosphorus-32 and paper chromatography to show the stimulating effect of glucose on phosphorus-32 turnover in muscle, kidney, liver and intestinal mucosa (*P*/1006).

In connexion with the skeleton, phosphorus-32, calcium-45 and sulphur-35 have been used to follow the metabolic processes of healing fractures (*P*/1500). The rapidity of concentration of calcium-45 in bone (commencing in 45 sec.), together with the rapid burying of calcium-45 and strontium-90 in the inaccessible regions of bone crystal (*P*/2397) and the demonstration of high concentrations of these isotopes in young Haversian osteons, all throw fresh light on the dynamic nature of bone metabolism. The metabolism of ruminants (*P*/813), the synthesis of milk (*P*/812) using carbon-14 labelled compounds and the isolated udder (*P*/852) have been investigated in detail. In connexion with hæmatology, the relationship of vitamin B_{12} labelled with radiocobalt to the intrinsic factors of the pig's stomach has been studied (*P*/1050), while in rats, incorporation of iron-59 has been used to study the factors influencing the formation of erythropoietin and to fix the kidney as its site of production (*P*/847). Survey autoradiograms of sections of whole mice have shown the distribution of various labelled drugs throughout the body (*P*/164), while in goats and cattle the metabolism of tritium-labelled hexœstrol has been demonstrated (*P*/280).

Several communications were concerned with radioiodine studies, and of these the relationship of the depression of central nervous activity due to damage to the pituitary or hypothalamus to inhibition of the thyroid seems important (*P*/2202). This has been investigated by the use of the defensive conditioned reflex, which has no effect in the absence of both the hypophysis and the adrenal. It would seem desirable that the conditioned reflex should be developed and used in other countries besides the U.S.S.R. as a tool for studying cortical function. Using this technique, it is stated that 0·5 μc. sodium-24 was a threshold dose for a rat, while to shorten the defensive conditioned reflex time to its initial level in 8–10 days a dose of 50 μc. of sodium-24 was effective (*P*/2056). Even tracer doses of iodine-131 are said to have significant effects.

Diagnostic measures using radioisotopes have become very numerous and varied. Iodine-132, with a half-life of 2·3 hr., permits early repetition of tests and, for the same precision, gives smaller doses to gonads, bone marrow and thyroid (*P*/277). It also makes possible the day-to-day following of conditions of iodine metabolism in the patient. Its preparation from tellurium-133 (half-life 77 hr.) is quite practicable. Much work has been done to elucidate thyroid metabolism. The etiology of thyroid disease and the scintillation mapping of the uptake of iodine have been improved. Pulmonary ventilation and circulation can be investigated alongside a cyclotron which can produce oxygen-15 with a half-life of 2 min. Decay of oxygen-15 is by emission of a positron, and the annihilation gamma-radiation can be measured by a scintillation counter externally (*P*/278). Small regions of the lung can be investigated, so that the method is an advance on bronchospirometry. Analysis of cardiac action has been advanced also by intravenous injection of radioiodinated serum albumin and also large-particle radiogold colloid. This latter is held by the lung capillaries and so normally excludes the circulation of the left heart (*P*/1385). Inhalation of krypton-85 and methyliodide-^{131}I has been used with the object of delivering a radioisotope to the left heart, so as to study the pure left-heart circulation (*P*/215) by external counting. Liver function has been studied by counting over the liver after the administration of rose-bengal labelled with iodine-131, since the liver cells take up the dye (*P*/870). The use of a new substance, di*iso*propylphosphofluoridate, for labelling blood cells has the advantage that it is not eluted from labelled cells and is chemically inert. The life of human erythrocytes, 110–130 days, was confirmed, and leucocytes and platelets, since they also contain esterases, also bind di*iso*propylphosphofluoridate (*P*/557). The use of iodine-131 and diiodofluorescin for improving accuracy of localization of brain tumours (*P*/2069) was reported in connexion with electroencephaloscopy. Automatic scintillography is becoming more widely used, and (*P*/1219) facilitates the mapping of organs containing gamma-radiators. The possibilities of quantitative estimation of elements subjected to neutron bombardment have been exploited in the case of arsenic determinations in hair, finger nails and tobacco (*P*/69).

Consideration of the radiation hazard has been the rule in almost all the techniques discussed. The physician and the investigator alike recognize their serious responsibilities for this aspect of work with radioisotopes. Methods of measurement have advanced so much that small trace quantities are the role, even for the scintillation scanning techniques. The measurement of bremsstrahlung from phosphorus-32 is a definite advance (*P*/1222) which may develop into a useful method.

In the therapeutic use of radioisotopes, no radically new procedures were reported. The selective uptake of boron compounds by brain tumours has been previously reported, and the work is being improved in detail. Boron-10 and lithium-7 have been concentrated to an effective degree in brain neoplasms, so that neutron capture can give a selective radiation effect on the tumours (*P*/881). The five-year results of the use of radiogold colloid intraperitoneally for ovarian cancer show a 45 per cent survival without symptoms from fifty-one patients. The results are the best yet published (*P*/234) for any series of ovarian carcinoma including all stages. Interstitial uses of radiocolloids of gold, yttrium and phosphorus have been explored by several workers. Uses of cobalt-60 for intracavitary treatments have been developed further (*P*/973). Attempts at destruction of the pituitary gland by grains of radiogold (*P*/68) and by radioyttrium pellets (*P*/874) are not by any means uniformly successful nor free from complications, although a stereotaxic method seems less liable to complications than fluoroscopic methods. Teletherapy units containing cobalt-60 have been developed so as to provide the advantages of high penetration, without excessive damage to skin and bone. There is no reason for expecting bone marrow to be spared by these high-energy beams. The differences in techniques necessary to use these advantages were discussed (*P*/67) and the relative merits of cæsium-137 as an alternative were mentioned (*P*/2403). At the same time, it was stated that 314 units containing in all 179,000 curies had been distributed by March 1958 to eighteen countries by Canada and the United States alone. Cæsium-137 for short-distance beam units was described (*P*/579).

Some results, for example, 45·4 per cent alive without symptoms for two to five years of cases of living cancer and 31 per cent of cases of cancer of the œsophagus alive without symptoms from one to three years (*P*/2056), are better than one finds in most countries.

F. ELLIS

General Uses

THE sessions on isotope applications at Geneva covered a very wide field. There were few revolutionary disclosures, perhaps because only a year has elapsed since the Unesco meeting on isotopes was held in Paris. Isotopes are now employed in some sixty different countries, and the papers accepted amounted to about fifty in each session, although only eight were read. The standard of the papers delivered was uneven, suggesting that their selection was made partly from political considerations and not solely on their scientific merit. The variety of topics covered makes classification under headings difficult, and in a brief report one can only suggest trends and pick out items here and there that caught the eye.

The monetary savings made by use of isotope applications run to large figures. Libby's estimate for 1957 savings in the United States is 500 million dollars (*P*/2390). A Russian survey gave their figure for 1957 as 1·5 billion roubles. The United Kingdom figures are still being analysed and are likely to be in the region of £1 million saved.

Of the materials produced, there have been improvements both in quantity and quality. A much greater range of labelled organic substances is offered. These are prepared by standard methods of synthesis, by biosynthesis using growing plants or algae to incorporate the labelled atoms, or by radiation labelling. This latter method attaches the labelled atom by an exchange reaction usually following ionization caused by gamma- or beta-bombardment (*P*/284). There is a significant increase in the use of tritium as a label. Iodine is still the medical tracer most used, its scope being widened by the short-lived isotopes now made (*P*/277). Many countries have plans to step-up their production of fission products from their power reactors. Cæsium-137 will be used for commercial radiations in million-curie quantities in a few years (*P*/831). The use of krypton-85 is expected to grow for applications in the oil industry and for exciting luminous signs and lamps (*P*/2520). Strontium-90 will also be on the same scale; but so far no one has suggested a satisfactory method of containment of this toxic substance without impairment of its beta-radiation. The demand for cobalt-60 is increasing steeply. There are 160 cobalt-60 therapy installations of 1,000 curies in the United States alone. Within a few years there will be several massive radiation cells in operation using 10^5 to 10^6 curies each.

In the field of massive radiation, greater caution was noticeable than in the predictions made at the first Geneva Conference (*P*/65). Preservation of foodstuffs has been found to have a number of drawbacks in practice. Some excellent Russian work has been done on the preservation of potatoes and the chemical effects of the radiation on the tubers (*P*/2131). Feeding trials in the U.S.S.R. have led the Ministry of Health there to permit irradiated potatoes to be sold and eaten by the public (*P*/2308). Other papers reported promising results from ante-mortem injection of adrenalin into meat to be irradiated by gamma-radiation (*P*/258). This arrests the enzyme activity and avoids unpleasant changes in flavour and smell.

Graft and block polymerization of plastics under gamma-bombardment may soon produce some important products (*P*/826). The United States papers reported a styrene–polyethylene ion-exchange membrane that has been used for purifying brackish water (*P*/2390). The possibility of coating some of the synthetic fibres to reduce their static attraction is of considerable interest to the textile industry. Improvements are reported from catalysts which are subjected to gamma-bombardment (*P*/2380).

A wide variety of industrial applications were reported at Geneva. In oil-well logging, radioactive methods are used as a standard technique. In 1957, eight million metres of oil boreholes were logged with neutrons. The movement of silt in harbours and estuaries can be measured with great sensitivity by depositing radioactive substances (*P*/2357). New methods of attaching the activity to sands and stones are being evolved, among them a Portuguese system of immersing sand in a radioactive silver solution which is later reduced by sunlight on the sand grains (*P*/1820). Measurement of flow in rivers, sewers and pipelines seems capable of application even on the largest scale. The recent method of total counts developed by Hull is a powerful variation of the usual technique (*P*/817). For tracing water through different strata, labelling by tritium, iodine or by cobalt complexes may show advantage in preventing the absorption of activity in the particular soils (*P*/1613).

Radiometric analysis is suggested as a control against toxic gases in the atmosphere (*P*/2390). The gas is made to react stoichiometrically with a radioactive reagent, and the resulting active product may be used to detect the gas quantitatively.

Several countries reported using tracers for mixing and flow studies to follow wood chips in pulp mills, and bulk flow in cement kilns, glass-works, etc. (*P*/1101). In most cases the measurement need only be made once, but it can give the information on hold-up and throughput-time vital to such processes.

Once again the papers from the U.S.S.R. showed their wide applications to the metallurgical industry (*P*/2218). Papers ranged from tests on mixing and melting times in steel furnaces and ladles to the study of micro-structure of alloys using autoradiography (*P*/2236).

In chemistry and biochemistry, the variety of labelled compounds has led to better understanding of chemical reactions and especially in carbohydrate, fat and protein metabolism. Thymidine, a precursor of deoxyribonucleic acid, has been labelled with tritium, so permitting autoradiography with clear enough resolution to study single cells or chromosomes (*P*/323). Further work continues on the mechanism of photosynthesis using chromatography and autoradiography. One method for following the path of oxygen starts with enriched stable oxygen-18. Later on, a chromatogram is bombarded by protons with the reaction $^{18}\mathrm{O}(pn)^{18}\mathrm{F}$ to allow the radioactive fluorine-18 to be measured (*P*/2520). Alpha-cameras were described for measuring thin paper, tissue or other microtome sections (*P*/1621). The surface densities measured were 10^{-14} gm./cm.^{2} with the claim that this could be improved to 10^{-15} gm./cm.^{2}.

A novelty was a Japanese method of using autoradiography to develop fingerprints by using formaldehyde or stearic acid labelled with carbon-14 on the protein traces in the print (*P*/1342). As the autoradiographs may require a week to develop it seems of questionable value for the speedy apprehension of a criminal.

In agriculture, work continues on the uptake of plant nutrients and the behaviour of ions in different soils (*P*/287). Of particular interest is the question of foliar sprays versus conventional root feeding (*P*/2390). Systemic insecticides and their subsequent fate in the plant are traced in the same way. Several nations described improvements to crops by selection of mutated strains. Gustafsson gave details of Swedish Pallas barley developed since 1947, which is an erectoid type having stiff straw and gives yields a few per cent better than its parent Bonus (*P*/2468). A Russian paper gave details of improvements in mutated types of streptomycin, aureomycin and terramycin which would save considerable amounts of money (*P*/2436). Even at the time of writing, some papers are still not available, and one looks forward to the publication of the official proceedings so as to re-read in comfort many of the contributions.

W. S. EASTWOOD

PROGRESS OF THE RUSSIAN EARTH SATELLITE *SPUTNIK* 3 (1958 δ)

By D. G. KING-HELE

Royal Aircraft Establishment, Farnborough

THE third Russian Earth satellite was launched on May 15, 1958, into an orbit which, like that of its predecessors, was inclined to the equator at an angle near 65°. On entering its orbit the satellite split into five pieces. The most important piece, carrying the instruments and radio transmitter, was roughly conical in shape, 12·3 ft. long and 5·7 ft. in diameter; it weighed 2,926 lb., including 2,134 lb. of scientific equipment, and was designated 1958 δ 2. The second and largest piece, 1958 δ 1, was the empty shell of the rocket which had carried the satellite into orbit; its shape and size have not been revealed. The other pieces, which have been observed only infrequently, are the nose cone and two side shields of the satellite.

Initially, the period of revolution of *Sputnik* 3 was 105·98 min. and the orbital eccentricity 0·111. The height above the Earth varied between 122 n.miles (226 km.) at perigee and 1,014 n.miles (1,879 km.) at apogee, with perigee occurring when the satellite was going north at a latitude of 50° N. Though *Sputnik* 3 and its rocket began in almost identical orbits, they were soon separated by the action of air drag, which had a much greater effect on the rocket than on the denser instrumented cone. Fig. 1 shows the period of revolution of the cone (curve *A*) and the rocket (curve *B*), with values of orbital eccentricity marked on the curves. The total life-time of the rocket is likely to be rather less than seven months, whereas that of the instrumented satellite is expected to be about twenty-one months

Though the rocket is due to make its final descent through the atmosphere early in December, its exact date of descent cannot be confidently predicted, be-

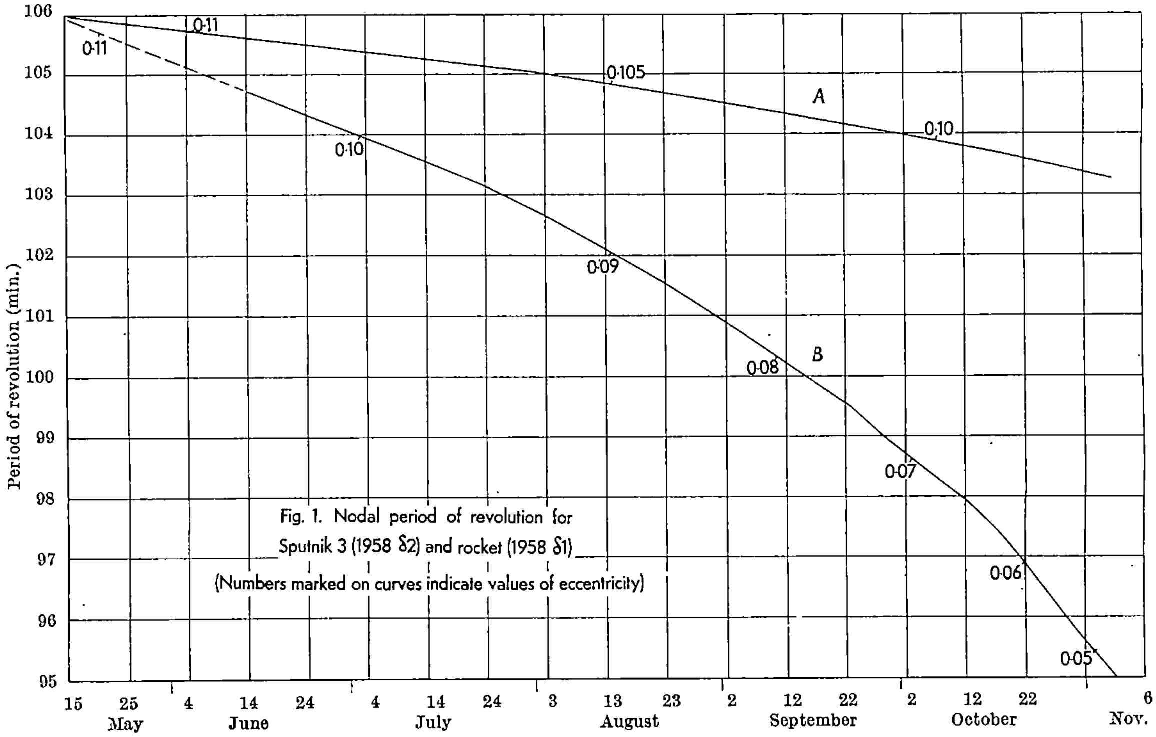

Fig. 1. Nodal period of revolution for Sputnik 3 (1958 δ2) and rocket (1958 δ1) (Numbers marked on curves indicate values of eccentricity)

cause the period has been decreasing in an irregular manner. The daily change in period, instead of increasing smoothly, has behaved more like a step-function: the change was about 2·4 sec./day from June 20 to July 20, about 3·2 sec./day from July 31 to August 19, about 4·0 sec./day from August 23 to September 22, about 4·8 sec./day from September 24 to October 10, and about 7·4 sec./day from October 19 to November 5. The daily change in period of the instrumented satellite has also exhibited sharp variations, though these are not so well charted, because observations have been fewer and the irregularities smaller: the change in period was about 0·7 sec./day initially and had risen to 1·1 sec./day by October 20.

An irregular decrease in period implies irregularities in either the effective cross-sectional area of a satellite or the effective air density near perigee. If, as is likely, irregularities in air density are occurring, does the density depend on latitude, on a parameter dependent upon time, or on some other influence? Comparison of *Sputnik* 3 and its rocket suggests that the density is more likely to be varying with latitude than with time[1]; but there is, as with[2] *Sputnik* 2, some indication of an oscillation having a period of about twenty-seven days, which might be attributed to lunar tides; and solar disturbances may have some influence[3].

The rocket has been a bright object in the night sky, occasionally reaching stellar magnitude − 2 on favourable transits. Because it is rotating, its brightness has fluctuated greatly, sometimes by a factor of more than 100. The period of the fluctuations has shown a slow increase, from 8·5 sec. in mid-July to 9·0 sec. at the end of August and 9·5 sec. at the end of October. The instrumented satellite is, as its designation 1958 δ 2 implies, less bright than the rocket, and observers have found it fickle in its

Table 1. ORBITAL DATA FOR *Sputnik* 3 (1958 δ 2)

Inclination to equator	65·19°	65·18°	65·17°	65·16°	± 0·04°

Table 2. ORBITAL DATA FOR *Sputnik* 3 ROCKET (1958 δ 1)

Date 1958	June 20·0	Aug. 4·0	Sept. 18·0	Nov. 2·0	
Nodal period (min.)	104·480	102·580	99·825	95·500	± 0·005
Semi-major axis (n.miles)	3965·4	3917·2	3846·7	3734·8	± 0·2
Eccentricity	0·1032	0·0925	0·0766	0·0506	± 0·0005
Perigee distance (n.miles)	3556	3555	3552	3546	± 2
Angle from apex to perigee	− 45°	− 61°	− 79°	− 97°	± 1°
Inclination to equator	65·17°	65·15°	65·12°	65·08°	± 0·04°

Notes: Apex is point of maximum latitude north. 1 n.mile = 6,080 ft. = 1·853 km. Last column gives estimated root-mean-square errors. No observations of 1958 δ 1 were made from Britain until mid-June.

behaviour: on some favourable transits it has remained obstinately invisible; at other times it has unexpectedly declared itself with flashes of stellar magnitude 1. It has not been necessary to rely entirely on optical observations, however, since the satellite has been transmitting radio signals on 20·005 Mc./sec., and these have, so far, continued with little diminution in strength.

Tables 1 and 2 give information on the orbits of *Sputnik* 3 and its rocket. The orbital inclination, like that[4] of *Sputnik* 2, has been decreasing slightly, probably as a result of lateral aerodynamic forces created by rotation of the atmosphere.

I wish to thank all those who have sent us observations of *Sputnik* 3 and its rocket, and Mrs. D. M. C. Walker, who has analysed the observations.

OBITUARIES

Prof. J. A. Gunn, C.B.E.

News of the death on October 21 of J. A. Gunn in his seventy-seventh year will have been received with sorrow by a wide circle of friends and by all pharmacologists who knew him.

Gunn was a true pharmacologist, not a physiologist in disguise; that is to say, his primary interest was in the physiological effects which chemical substances foreign to the animal economy, whether synthetic or of plant origin, produce in animals. This interest led him to ponder deeply upon some of the problems presented by what we now call the structure – action relationships of drugs. In this he was probably influenced by his teacher, Sir Thomas Fraser, who, with his chemical colleague Crum Brown, had made the first systematic attempt to study the structure – action relationships of drugs. It was with Fraser that one of Gunn's earliest papers on "Venoms" was published. At the same time, in the true Scottish tradition, Gunn never forgot the therapeutic possibilities of the substances which he happened to investigate.

Gunn's general point of view was clearly stated in a short review, published in 1935, of his work on the alkaloids of *Peganum harmala*; this paper not only reveals his philosophy as a pharmacologist but is also an excellent example of his lucid and elegant prose style. He was the acknowledged authority on the pharmacology of the harmine alkaloids, on the study of which he was engaged intermittently for twenty-five years. When he began this work the structures of these alkaloids were unknown, but the brilliant investigations of W. H. Perkin, jun., and of Sir Robert Robinson eventually solved the structural problems, and Gunn profited from this work by receiving from Sir Robert Robinson several new and interesting derivatives of the natural alkaloids.

Gunn was the first professor of pharmacology to be appointed in the University of Oxford, and later became the first director of the Nuffield Institute for Medical Research. It is of some interest that he was convinced that every department of pharmacology ought to have a chemist on its staff. For a few years he was fortunate in having an able young chemist, Dr. C. J. Virden, in his Department, and the result of their collaboration was a series of papers on sympathomimetic amines. Gunn was the first to study the pharmacological effects of alkylating the phenolic groups of *para-* and *meta*-hydroxy- and 3 : 4-dihydroxy-phenylalkylamines. Even more interesting was his observation that the replacement of the β-methylene group of phenyl-ethylamine and *-iso*propylamine by an ethylene unit of structure scarcely altered, either qualitatively or quantitatively, the pharmacology of these bases.

Apart from his teaching and research activities. Gunn edited several editions of Cushny's great monograph on pharmacology after the latter author's death; he also wrote an admirable short book on pharmacology from which many generations of medical students have profited; the last edition, in which J. D. P. Graham collaborated, appeared shortly before his death. He was also for many years a member, and later chairman, of the Pharmacopœia Revision Commission, an arduous duty which he took very seriously. British pharmacology owes him a debt of gratitude, not least because the young, but flourishing, British Pharmacological Society owes its origin to his suggestion. Finally, his unselfish nature led him to take a great interest in the careers of young men, and there must be many well-established pharmacologists to-day who owe much to his encouragement and help, and who will remember him with affection and respect.

H. R. Ing

Prof. Stanisław Loria

The death on August 8 of Stanisław Loria is a great loss to Polish physics. He was one of the older generation of physicists, who knew well almost all the great men of the first half of our century. He knew Lorentz and Ehrenfest, and studied with Born and Ladenburg in Breslau. (Usually Prof. Born's first words to me, whenever we met, were: "How is Loria?") He worked in Manchester under Lord Rutherford, and during 1923–26 was a research associate in Pasadena, where he had been invited by Prof. R. A. Millikan. He was well acquainted with the old centres of research. It was a delight to hear him talking about his great teacher Witkowski, about Smoluchowski and Natanson, professors of physics in the old Jagellonian University of Cracow, about Madame Skłodowska Curie, about all the great physicists whom he knew personally and whom the present generation know only from the literature.

Stanisław Loria was born in 1883 in Warsaw. He went to high school and took his university degree in Cracow. In this former Polish capital, then a part of the Austrian Empire, the Polish language was not banned either from the high schools or from the University. There he received his Ph.D. and went for further studies to Wrocław (then Breslau). Göttingen and Berlin, where he spent the years 1907–10. At this time, with Ladenburg, he discovered the phenomenon of anomalous dispersion in hydrogen; the first note on this important effect appeared in *Nature* in 1908.

In 1910 he became a reader (*docent*) in physics in the University of Cracow and in 1919 a professor of physics in the University of Lwów. There he remained until the Second World War—with long intervals devoted to research in laboratories abroad. Even through the War he was in Lwów—up to 1941, when the Germans occupied the town. His last work before the War concerned the problem of diffraction of electrons with energies between 18,000 and 4,500 volts. Unfortunately, it was only partially published, since the apparatus and notes were taken away or destroyed by the Nazis. Prof. Loria had to hide during the German occupation. In free Poland he was a professor in Wrocław and later in Poznań. He died in a London hospital, where he had undergone an operation.

During his life Prof. Loria was very much interested in theoretical physics; he was one of the first physicists who studied Einstein's paper of 1905 and, some years later, wrote in his vivid style a book on relativity theory, the first that appeared on this subject in Poland.

Prof. Loria will be remembered by many Polish physicists. Some of them, including the present writer, owe to his encouragement and help the beginning of their academic careers.

LEOPOLD INFELD

Mr. E. W. Swanton, O.B.E.

MR. ERNEST WILLIAM SWANTON died at Twickenham on October 21 at the age of eighty-eight. After spending his early years as a schoolmaster and private tutor, Swanton was in 1897 appointed the first curator of the Educational Museum at Haslemere, which had been established in 1888 by Mr. (later Sir) Jonathan Hutchinson, a well-known London surgeon. Hutchinson had many novel ideas on the value and arrangement of museums for educational purposes, particularly in the use of living material, the open display of specimens so that they could be handled and in making objective teaching "within the easy ken of all ordinary minds". It was Swanton who was mainly responsible for putting Hutchinson's ideas into practice, 'and so successfully did he build up the educational work that S. F. Markham, in his "Report on the Public Museums of the British Isles", was able to say in 1938: "At Haslemere possibly more educational work of this kind is done than in any comparable museum centre in the country".

In 1898, a few months after his appointment as curator, Swanton began to give regular series of lessons in natural history to children from the local elementary schools, illustrating his lectures by handing around specimens from the Museum collections—an early, if not the earliest, use of museums by organized parties of school-children in this way, and a tradition that has been continued at Haslemere to the present time. In 1899, Swanton organized another feature originated by the founder, which he continued throughout his curatorship: a museum examination for individual local children in which, after several months preparation in the museum galleries in their own time, they were called upon to answer an examination paper covering the whole scope of natural and human history. This was widely hailed as a new contribution to museum teaching techniques.

Swanton had wide antiquarian and natural history interests, but he will be remembered chiefly as a field mycologist. In 1898 he was a foundation member of the British Mycological Society and became its president in 1916. The Society had many notable forays in the Haslemere district with Mr. and Mrs. Swanton as genial hosts. In 1909 he published a useful popular handbook, "Fungi and how to Know Them", which had a second edition in 1922. Among his other publications were "A Pocket Guide to the British Non-Marine Mollusca" (1906), "British Plant Galls" (1912), "A Country Museum" (1947) and, jointly with P. Woods, "Bygone Haslemere" (1914). In the last year of his life he wrote and had privately printed three small books, "A Brief Autobiography", "The Yew Trees of England" and "Memories and Notes".

Swanton was elected an associate of the Linnean Society in 1920, and in 1936 his work at the Museum was recognized by his appointment as M.B.E.; he was advanced to O.B.E. in 1948, the year when he retired. In 1949 he was granted a Civil List pension. His wife, whose help in the work of the Museum he frequently acknowledged, died in 1957.

JOHN CLEGG

NEWS and VIEWS

Royal Medals of the Royal Society

H.M. THE QUEEN has been graciously pleased to approve the recommendations made by the Council of the Royal Society for the award of the two Royal Medals for 1958 as follows: to Prof. H. S. W. Massey, Quain professor of physics at University College in the University of London, for his distinguished contributions to physics, and particularly for his experimental and theoretical studies of collision phenomena in gases; to Prof. A. L. Hodgkin, Royal Society research professor, for his distinguished work on the mechanism of excitation and conduction in nerve and muscle.

Directorship of Dunsink Observatory: Dr. M. A. Ellison

DR. MERVYN A. ELLISON, principal scientific officer at the Royal Observatory, Blackford Hill, Edinburgh, since 1947, has been appointed senior professor of astronomy at the Dublin Institute of Advanced Studies and director of the Dunsink Observatory, situated a few miles from Dublin. Dr. Ellison spent his early years in Ireland, first in the south where he was born in 1909, and later at Armagh Observatory, where his father, Canon W. F. A. Ellison, well known for his astronomical optical work, was director during 1918–36. After graduating at Trinity College, Dublin, in 1932, he taught for some years at Sherborne and successfully pursued his study of solar phenomena in his leisure time, until his appointment at Edinburgh enabled him to devote himself completely to this work. He has published a series of papers on solar flares and their terrestrial effects and on stellar scintillation, which have brought him international recognition, and is the author of a well-known book on "The Sun and Its Influence", which has been translated into several languages, including Russian. He is popular as a lecturer and broadcaster and is president of the Astronomical

Society of Edinburgh. Dr. Ellison is correspondent for solar activity of the British National Committee for the International Geophysical Year and has just been elected to succeed Dr. Y. Öhman, of Sweden, as international reporter for solar activity. After the death of Prof. W. M. H. Greaves and until the appointment of Prof. H. A. Brück as his successor (see *Nature*, 179, 454; 1957), Dr. Ellison served for nearly two years as acting director of the Royal Observatory, Edinburgh. He now succeeds Prof. Brück in the post at Dunsink.

A Commonwealth Overseas Research Council

Lord Home, Secretary of State for Commonwealth Relations, announced at the Commonwealth Trade and Economic Conference in Montreal on September 24 that an Overseas Research Council is to be established to aid Commonwealth countries in scientific research. The United Kingdom Research Councils—Department of Scientific and Industrial Research, Medical Research Council and Agricultural Research Council—are willing, he said, to provide advice and assistance on research matters falling within their respective fields to any Commonwealth country requiring such assistance, wherever this can be done within the funds available. The Overseas Research Council will provide for the co-ordination of this assistance. It will advise Ministers on questions of co-operation in scientific research overseas and will also provide a central point to which Commonwealth Governments and research institutions can refer for advice and information.

The International Atomic Energy Agency : Scientific Advisory Committee

The Board of Governors of the International Atomic Energy Agency has appointed the following to serve on the Agency's Scientific Advisory Committee: Prof. H. J. Bhabha (India) (subject to the concurrence of the Government of India); Sir John Cockcroft (United Kingdom); Prof. V. S. Emelyanov (U.S.S.R.); Prof. B. Goldschmidt (France); Prof. B. Gross (Brazil); Prof. W. B. Lewis (Canada) and Prof. I. I. Rabi (U.S.A.). The function of this Committee is to provide the Board and the Director-General of the Agency with advice on scientific and technical questions arising out of the Agency's programme. The members are appointed in their personal capacity, with the concurrence of their respective governments. Membership of the Committee is identical with that of the Scientific Advisory Committee of the United Nations, and it is expected that this fact will still further strengthen the relationship between the International Atomic Energy Agency and the United Nations.

Nuclear Safety Advisory Committee

In moving the second reading of the Nuclear Installations (Licensing and Insurance) Bill in the House of Lords on November 13, the Minister of Power, Lord Mills, said that he and the Secretary of State for Scotland had decided to appoint a Nuclear Safety Advisory Committee composed of experts of the highest standing. They regarded such a Committee as necessary in view of the rapid strides which nuclear science and engineering were making and the consequent continuous evolution of the attendant problems of safety. In making appointments to the Committee, they intended to consult, *inter alia*, the Atomic Energy Authority, manufacturers of nuclear plant, the insurers, and the owners and operators of major nuclear installations. They had decided to establish this Committee administratively rather than by statute because developments in the industry were hard to foresee and might eventually necessitate changes in the constitution of the Committee or its terms of reference and such changes would thereby be more easily made. Referring to the exemption of the Atomic Energy Authority from licensing under the Bill, Lord Mills explained that the Authority's work was mainly experimental. To include it, apart from involving delays, would require a much larger inspectorate and also inspectors as expert in advanced research as the Authority's own scientists. Government departments would not normally be subject to licensing, but it was intended that they should follow the safety principles evolved between the Minister, the Atomic Energy Authority and the Nuclear Safety Committee and they would be under the same third-party liability as the Authority. Replying to questions in the debate, Lord Mills added that the Bill did not cover the question of hospitals or the manufacture of pharmaceuticals, nor was it intended to cover ordinary university research or similar activities. If and when these activities required cover, fresh measures would be laid before Parliament.

Moon Rocket Tracking

A 108-mc./s. interferometer with a base line of 80 wave-lengths was used by the Royal Aircraft Establishment of the Ministry of Supply on November 8 to track the third American Moon rocket. A satisfactory record was obtained during 07.47–08.01 G.M.T., that is, for the time the rocket was above the horizon as seen from Great Britain. When the complete analysis is available the bearing of the rocket from Lasham, Hampshire, where the interferometer is located, will be known at every instant during this period with an accuracy of about 1 sec. of arc—an accuracy in position of approximately 10 miles at 4,000 miles range. Since the launching point is known, it should be possible to determine the complete orbit of the rocket, and by extrapolation to make a very fair estimate of the area where any surviving pieces may be. It is interesting to note that observers at Lasham realized at 07.55 that the missile had gone astray, since the type of record obtained was similar in character to those for the American Earth satellites. It is a feature of this equipment that a rapid assessment of the missile projectory is possible. The accuracy of bearing realizable with a fixed aerial equipment of this type is some hundred times greater than is possible with types of steerable aerials.

Central Agency for Carbon-14 Determination

During recent years, the study of primary production in the sea has been followed by radioactive tracer methods using carbon-14, a technique first employed by Nielsen. The method is very useful in that the field-work does not presuppose any expert knowledge of radiochemistry. On the other hand, manufacture of the necessary ampoules of sodium bicarbonate solution labelled with carbon-14, and the measurements of the radioactivity of the resulting filters, do require the facilities of a well-equipped radiochemical laboratory. In order to make such facilities available to the smaller marine laboratories, the recommendations adopted at the 1957 Bergen symposium on "Measurement of Primary Production in the Sea" have now been implemented and a central agency has been set up at Charlottenlund Slot, Denmark. This has been made possible by the provision of funds by Unesco in January 1958, and of a room in its residence at Charlottenlund Castle by the Danish Institute for Fisheries and Marine Research. Prof. E. Steemann Nielsen, adviser in plankton research for that Institute, has been appointed honorary supervisor, and the daily work will be directed by Mr. Vagn Hanson, also of the same Institute. The facilities of the Agency are available to all scientific institutions in the world, and as well as providing the service mentioned above, the Agency also supplies the necessary ancillary equipment for use in the field. Full details can be obtained from Prof. E. Steemann Nielsen, The International Agency for Carbon-14 Determination, Charlottenlund Slot, Charlottenlund, Denmark.

British Information Services

QUESTIONS in the House of Commons on November 3 regarding the improvement of British information services overseas brought a reply from the Chancellor of the Duchy of Lancaster, Dr. Charles Hill. He said that as a result of his visit in September to information posts in India, Pakistan, Aden, British Somaliland, Kenya, Ethiopia and Somalia, he had formed the conclusion that we should intensify our effort, adapt it to new circumstances and increase the resources available. He referred particularly to the need to counter hostile radio propaganda, to increase the flow of British books, and to expand the programme of teaching English. The Government has approved in principle a substantial strengthening of our information effort, and plans are now being worked out. He hoped to report in detail in a few weeks time, and in reply to a further question promised to consider the issue of a White Paper showing the progress made in implementing earlier proposals. That relating to the distribution of English books overseas was particularly welcomed.

High-Altitude Research

IN reply to questions in the House of Commons regarding Earth satellites on November 3, the Minister of Supply, Mr. Aubrey Jones, said that the *Black Knight* is a test vehicle for high-altitude research, and a programme of further firings is planned. The opportunity for space research arises from certain techniques being developed for the defence programme. His officials are in constant touch with the Office of the Lord President of the Council and numerous scientific authorities on the scientific value to be obtained from British participation in space research, including research investigations by satellites. The scientific value and not finance is the real question at issue, and the possibility of co-operation with other countries is also taken into account.

Salaries of Teachers in Technical Institutions

ONE of the main recommendations of the committee which, under the chairmanship of Sir Willis Jackson, met to consider the supply and training of teachers for technical institutions was the need to recruit people of good calibre from industry. Perhaps the greatest deterrent is the disparity between the salaries paid to technical college teachers and their colleagues in industry. This matter has been considered recently by the Association of Teachers in Technical Institutions, leading to a memorandum which has been submitted to the Teachers' Panels of the Burnham Main Committee and the Burnham Technical Committee.

The main recommendations include the abolition of all grade *A* assistant posts in technical institutions and that all teachers holding these positions should become assistants grade *B*; this grade should be renamed 'assistant lecturer'. The remaining grades of teacher should remain substantially as at present except that the grade of 'reader' should be renamed 'principal lecturer' and be available for research, advanced teaching or administrative responsibility in all colleges doing work of university standard. A new grade of deputy head of department should be established for large departments. For all these grades there should be increases in salary in appropriate relation to the increases given to assistant lecturers. The Association also proposes the establishment of national scales of salaries for part-time teachers, based on the principle that the cost of carrying a given teaching load should be the same whether the work is done by part-time or full-time teachers.

Unesco Programme for Arid Lands

UNESCO Information Manual 3 contains a concise, clear and readable account of the Unesco Programme for Arid Lands (pp. 31. Paris: Unesco; London: H.M. Stationery Office, 1958). Commencing with a statement of the nature and extent of the problem presented by the arid zones, representing about one-third of the Earth's total land surface of 33,000 million acres, compared with the 3,300 million acres under cultivation, the pamphlet briefly describes the way in which the problem has been attacked by Unesco during the past ten years, its search for facts, the steps taken to inform the scientific world, through, for example, a Directory of Institutions engaged in Arid Land Research and a Guide Book to Research Data for Arid Land Development, and the way in which the attack on the desert has now become a major project of Unesco. Steps taken to develop water resources are indicated, including the use of artificial means for provoking rainfall, demineralization of salt water, studies in plant ecology of the arid zone, and the harnessing of sun and wind, and the pilot project to study the social adjustment of nomadic and semi-nomadic groups to settled existence. An outline is given in the 1957–58 programme. The pamphlet contains a bibliography and a select list of visual aids on a subject in which, besides the International Council of Scientific Unions and several of the individual unions, the Scientific Council for Africa South of the Sahara, the World Power Conference and a number of other international bodies are already interested.

The Analyst

THE earliest ten volumes of *The Analyst*, for the years 1876–85, have been re-published in facsimile form by W. Heffer and Sons, Ltd., of Cambridge, who are the publishers of the journal on behalf of the Society of Analytical Chemistry. These volumes cover the early years of the operation of the Sale of Food and Drugs Act, 1875, and are of considerable historical importance. During these ten years chemical analysis passed from the sphere of the dilettante chemical investigator to that of an exact science, capable of legal argument and applicable on an industrial scale. The analysis of water was systematized, and the beginnings of biological examination are described in many of the papers. The Society whose journal this is, although then named 'The Society of Public Analysts', has catered from its inception for all classes of analyst; for example, Vol. 1 contains papers on the analysis of coal and of plating and gilding solutions, as well as much work on various foods. Each volume is available separately from any bookseller or direct from the publishers at 6 guineas, bound in cloth boards in the style of the original. Publication in America is through the Johnson Reprint Corporation.

The Wellcome Museum of Medical Science

SINCE it was opened by the Wellcome Foundation in 1914, the Wellcome Museum of Medical Science in Euston Road, London, has provided a unique display of photographs, specimens and extracts from medical literature, which give, in study units housed in comfortable and attractive bays screened off from the rest of the Museum, comprehensive information about each of the diseases dealt with (see "The Wellcome Museum of Medical Science". Pp. 40. London: The Wellcome Foundation, Ltd., 1958). Some 10,000 doctors, nurses, medical missionaries and students visit the Museum each year from all parts of the world. Originally the Museum was devoted largely to tropical diseases, but nowadays it covers a much wider field. Recently reorganized, it now reflects the changes in emphasis on certain diseases which have resulted from the remarkable advances in control and treatment that have been made in recent years. Thus, the thirty-two panels formerly given to syphilis have now been reduced to four, and the seven panels given earlier to plague have been reduced to three. Cholera also is no longer feared as it used to be. Malaria, however, still occupies forty-two panels, though if the schemes for its control and eradication continue to succeed as they have done during the past five years, much less space will be needed to cover this disease, which has for long been the greatest single cause of illness and death in the world. Tuberculosis, on the other hand, is likely to be given more space to illustrate its importance in the tropics. A pleasing feature of the Museum's activities is the use that is made of it by boys' and girls' schools, to which the Museum lends suitable selections of material for the stimulation of interest in biology. It also lends or gives exhibits to medical schools throughout the Commonwealth. Last year a section of the Museum was shown in Durban, South Africa, and another section, devoted to trypanosomiasis in Africa and South America, was shown at the sixth International Congress on Tropical Medicine and Malaria at Lisbon.

Systematics of Parrot-fishes

THE brightly coloured parrot-fishes are ubiquitous denizens of coral reefs throughout the tropics. For feeding on coral the dentition has been greatly modified, with fusion of the teeth in the front of the jaws into a pair of dental plates forming the 'parrot's beak' from which these fish get their name. The pharyngeal musculature is highly developed and operates a mill formed of grinding teeth on the pharyngeal bones. Many of the species have a large swelling on the forehead which adds to their bizarre appearance. In the past, the systematic description of this group has been highly confused and more than 350 species have been named and described. In a recent publication (U.S. National Museum, Bulletin 214: Review of the Parrotfishes, Family Scaridae, by L. P. Schultz. Pp. v+143+27 plates. Washington, D.C.: Government Printing Office, 1958. 75 cents), the curator of fishes of the United States National Museum has done much to unravel the confused systematics of the parrot-fishes. He claims that only eighty species can be regarded as valid. Many of the large number described, he points out, have been erected into so-called species on the basis of colour patterns which vary not only between individuals but between different stages in the life-history of one individual, while there is also a sexual dichromatism. His review of the Scaridae at last places this family in some sort of perspective and demonstrates their relationship with the labrid fishes. There are excellent keys to genera and species.

Dormancy in *Viburnum* Seeds

IN an investigation of dormancy in the seeds of *Viburnum trilobum*, R. H. Knowles and S. Zalik (*Canadian J. Bot.*, 36, 561; 1958) have observed this phenomenon in seedlings as well as in seeds. When seeds were maintained at 20° C. under suitable conditions for germination, there was slow growth in the radicle and hypocotyl in some seeds, while others showed no response. They have found that this kind of dormancy is associated with the presence of a water-soluble inhibitor in the endocarp and with the need for an appropriate (inductive) temperature treatment prior to exposure to a constant 20° C.; they also found that dormancy in the epicotyl, namely, failure of shoot growth in the young seedling, could be overcome by removing the cotyledons.

Tropical Karst

LANDFORMS developed in regions of massive limestone or dolomite where erosion is principally by solution of the rock rather than mechanical corrasion have long been known as 'karst' from the area in Yugoslavia where they were first investigated. The karstlands of temperate latitudes have received considerable attention, but their occurrence in tropical areas has been less closely studied. In an article in the *Geographical Journal* (124, part 2, 184; June 1958) Dr. Marjorie Sweeting gives an admirably lucid account of its distribution and characteristics in Jamaica. She shows that even in an area of pure, free-draining limestone an annual rainfall of 100 in. or more is sufficient to maintain a heavy forest cover and that water passing through this cover is so highly charged with organic carbon dioxide that the solution rates may be 400 per cent greater than in cooler climates. The most characteristic land-form produced under these conditions is 'cockpit karst', in which the entire surface is covered by conical depressions, here 300–400 ft. deep, separated by cone-like hills. There are no watercourses on the surface. Where the crystalline white limestone passes into other formations and free vertical drainage is checked, solution and sapping takes place along the base and sides of the cockpits and the mechanical effect of flood water in undercutting and steepening the sides is considerable, and 'tower karst' develops. Dr. Sweeting indicates that in areas of more marly limestone and lower rainfall dolines and poljes, already well known from European examples, develop. She gives some attention also to associated caves and underground river systems.

Mond Nickel Fellowships

THE Mond Nickel Fellowships Committee recently announced the award of fellowships for 1958 to the following: Mr. G. H. Longworth (Lancashire Steel Manufacturing Co., Ltd.) to study the manufacture of plain carbon and alloy steels for rod and wire products in the United Kingdom, on the Continent, and in the United States; Mr. J. C. Morrison (Carron Company) to study melting, moulding and heat treatment of alloy cast irons, quality control of metal and sand plants in modern foundries, and new developments in related metallurgical processes; Mr. T. Tait (Colvilles Limited) to study the technical and economic factors involved in the use of oxygen in steel industries in the United Kingdom, on the Continent, and in the United States and Canada.

The Mond Nickel Fellowships Committee is offering one-year fellowships valued at £900–£1,200 for 1959, to graduates of British nationality to enable them to obtain wider experience and additional training in industrial establishments, in Britain or abroad, to make them more suitable for future employment in senior technical and administrative positions in British metallurgical industries. Applicants will be required to state details of the programme they wish to carry out. Particulars and forms of application are available from the Secretary, Mond Nickel Fellowships Committee, 4, Grosvenor Gardens, London, S.W.1.

Mechanization of Thought Processes

A symposium on "The Mechanization of Thought Processes" is being held at the National Physical Laboratory, Teddington, during November 24–27. More than two hundred delegates will be attending. After opening sessions on general principles, succeeding sessions will be devoted to automatic programming, language translation, speech recognition, learning in machines, and implications for biology and for industry. Further information can be obtained from the Chief Information Officer, Department of Scientific and Industrial Research, Charles House, 5–11 Regent Street, London, S.W.1.

United Nations Conference on Peaceful Uses of Atomic Energy: Proceedings

The United Nations have announced that the pre-publication period for the Proceedings of the Second U.N. International Conference on the Peaceful Uses of Atomic Energy, during which complete sets may be ordered at a special price, has been extended to January 31, 1959. The action was taken to facilitate the budgetary arrangements of institutions unable to purchase the complete set of volumes from their 1958 budgets. Until January 31, the thirty-three volumes of the English edition may be ordered for 435 American dollars, £155 sterling, or 1,860 Swiss francs. The special pre-publication price for the complete set represents a saving of some 70 dollars as compared with the regular price of the set. For the French and Spanish editions, each of which is expected to include approximately fifteen volumes, the special pre-publication price will be 190 U.S. dollars, £68 sterling, or 815 Swiss francs. If the number of volumes is less than fifteen, proportionate refunds will be made to subscribers who have ordered a full set. Further information can be obtained from the United Nations, Sales and Circulation (Atomic Energy), United Nations, New York.

The de Havilland Aircraft Co., Ltd.: Appointments

Mr. R. G. McCoy has been appointed general manager of the de Havilland Aircraft Co., Ltd., with effect from December 1. He joined the company in May 1953 as deputy service manager, becoming manager in April 1954, and was responsible for the Service Department until July 1958, as well as acting as assistant to the managing director from January 1956. Mr. D. R. Newman has been appointed chief aerodynamicist of the company with effect from December 1. Mr. M. Herrod-Hempsall remains responsible for administration in the Aerodynamics and allied Departments. Mr. Newman joined the de Havilland Aeronautical Technical School in April 1936 and has been in the Aerodynamics Department since May 1938.

Announcements

Prof. E. E. Zepler, professor of electronics in the University of Southampton, has been elected president of the British Institution of Radio Engineers for 1958–59.

Sir Walter Drummond has been appointed chairman of the Farm Buildings Research Committee of the Agricultural Research Council, in succession to Lord Rothschild. The Farm Buildings Research Committee has been set up by the Council to co-ordinate the different research activities concerned with farm buildings and to advise on their further development.

The 125th meeting of the American Association for the Advancement of Science will be held in Washington, D.C., during December 26–31, with headquarters in the Sheraton-Park Hotel. In addition to the eighteen sections of the Association, about ninety-two affiliated and associated societies will participate. The presidential address, on "Fifty Years of Medical Genetics", will be delivered by Dr. Laurence H. Snyder, president of the University of Hawaii, and retiring president of the Association. Further information can be obtained from Sidney S. Nagus, Medical College of Virginia, Richmond, Virginia.

A group of experts from Australia, Germany, Iran, Portugal, South Africa, United Kingdom and the United States is meeting, under the auspices of the Food and Agriculture Organization and the Office International des Epizooties, to consider problems of ticks and tick-borne diseases. The meetings are being held during November 24–29, at the Royal College of Veterinary Surgeons in London. Further particulars can be obtained from the Registrar of the College, 9 and 10 Red Lion Square, London, W.C.1.

The 129th course of six Christmas lectures "adapted to a juvenile auditory" will discuss the International Geophysical Year, and is to be delivered at the Royal Institution on December 30, 1958, and January 1, 3, 6, 8 and 10, 1959, at 3 p.m. The lectures are as follows: "The Ionosphere and the International Geophysical Year", by J. A. Ratcliffe; "Geomagnetism", by J. M. Stagg; "Exploration of the Upper Atmosphere", by Dr. R. L. F. Boyd; "Meteorology", by Sir Graham Sutton; "Oceanography in the International Geophysical Year", by Dr. G. E. R. Deacon. Applications for tickets (juveniles, aged 10–17, £1; adult non-members, £2) should be addressed to the Royal Institution, 21 Albemarle Street, London, W.1.

A symposium on "Experimental Approaches to the Problems of Growth and Form in Plants" is being held in the rooms of the Linnean Society of London during December 19–20. This is being arranged by the Experimental Plant Morphology Group of the Society and the Symposium is open to visitors. Further information can be obtained from the Secretaries, Linnean Society, Burlington House, Piccadilly, London, W.1.

THE WORLD REFERENCE LABORATORY FOR FOOT-AND-MOUTH DISEASE

THE control of diseases of livestock is an important feature in the general economy of most countries in improving animal production and in fostering international trade in livestock and animal products. Foot-and-mouth disease is one of the most troublesome of the infectious diseases of livestock, and increasing attention is now being given on an international basis to its control and eradication.

It is gratifying to learn in this connexion that one of the recent steps taken, following negotiations between the Food and Agriculture Organization of the United Nations and the British Government, has been the establishment of a World Reference Laboratory for Foot-and-Mouth Disease at the Research Institute (Animal Virus Diseases), Pirbright, Surrey, which functions administratively under the ægis of the Agricultural Research Council.

It is particularly appropriate that the Pirbright Institute should have been asked to accept this responsibility because of its experience in the examination of virus material from all over the world during the past ten years and because it has all the necessary facilities for the full examination of suspect material.

The Institute reported recently the results of the examination and immunological classification of 2,200 virus samples from outbreaks in countries in Europe, Africa, Asia and the Americas. This must be considered only as a useful first contribution to a very big epizootiological problem as there are many areas which have not yet been covered. A satisfactory epizootiological world picture cannot be produced until a reasonably large number of samples have been examined from outbreaks in as many countries as possible. The Food and Agriculture Organization is seeking the co-operation of governments so that the surveys carried out for a number of countries will be continued and extended. It is hoped that one of the immediate results of this will be the continued collection and dispatch to the World Reference Laboratory, now established, of suitable field samples from outbreaks of the disease in countries all over the world.

The virus of foot-and-mouth disease, unlike those of yellow fever and rinderpest, is characterized by the lack of antigenic homogeneity. There are at present seven main immunological types of the virus (compared with three in poliomyelitis, three in influenza, three in equine encephalomyelitis and two in vesicular stomatitis). The well-known types *O*, *A*, and *C* (1922–26) have been found in Europe, the Americas, Asia and Africa, and the work of the Pirbright Institute has brought to light four other types, three (*S.A.T.*1, *S.A.T.*2 and *S.A.T.*3) at present known only in Africa but one as far north as Egypt, and the fourth, *ASIA* 1, only in Asia but as far west as Iran and Israel. It is possible that other types of the virus may be discovered as the result of more extended surveys. There are, in addition, strains of the virus within each main immunological group which differ sufficiently in antigenic constitution to classify them as variants or sub-types. Control programmes in many parts of the world include vaccination, and an essential to make these effective is accurate information on types and strain differences, so that appropriate vaccines can be used.

It is universally recognized that there is considerable advantage in having a central laboratory which is in a position to collect information on the distribution of virus types responsible for outbreaks, sporadic, enzootic and epizootic, and to complete surveys by collecting essential information on the character of outbreaks, the number and species of animals involved, the possible origin of outbreaks and other relevant details. The resulting epizootiological picture would be of much value in organizing methods of control and eradication and in assisting countries to estimate risks associated with trade. Reports of the world position will be issued through the Food and Agriculture Organization from time to time.

The functions of the World Reference Laboratory will include also the examination and classification of virus types and sub-types, the ultimate establishment of a collection of all types and confirmed sub-types and their corresponding antisera. It is not intended that the World Reference Laboratory should undertake the routine examination of virus material from European countries or the Americas, since there are already facilities for this purpose. The World Reference Laboratory will, however, give all possible assistance if specially requested to do so and will be assisting with the sub-type classification problem and be responsible for the examination and identification of strains of virus suspected to be other than types *O*, *A*, and *C*.

THE NATIONAL VEGETABLE RESEARCH STATION

REPORT FOR 1956–57

THE eighth annual report* of the National Vegetable Research Station, recently published, provides a summary of the progress made by the eight sections of the Station. Some of our common vegetables are receiving the attention of the plant breeders, and further advance has been made in selecting a non-bolting type of red beet having single-seeded fruit. The production of onion and brussels sprout hybrids and a winter-hardy culinary pea is also being pursued. A report by L. E. Watts and R. A. T. George on a two-year investigation of the classification and performance of radishes involved the testing of 114 varieties made up of approximately equal numbers from British and foreign sources. An appendix to this report gives a classification and grouping of radish varieties. The authors conclude that there is no urgent need for a breeding programme for this vegetable as commercial varieties of satisfactory quality are already available.

---

* British Society for the Promotion of Vegetable Research. Eighth Annual Report, 1957 (October 1956–September 1957). Pp. viii+67. (Wellesbourne, Warwick: British Society for the Promotion of Vegetable Research, 1958.)

The Chemistry Section has continued the analysis of the long-term field experiments and investigated the effect of different manurial treatments on soil structure. An examination of the biochemical factors affecting the germination of seeds was commenced. The chemical changes occurring in the root of red beet when clamped and during flowering are being studied. The nature of the competition between weeds and vegetables is one of the problems being investigated in the Physiology Section, which is also concerned with growth studies of vegetable crops with the object of finding how various manurial treatments affect the growth and yield of crops. The influence of various treatments on the flowering of vegetables is being studied. In the Irrigation Section emphasis is shifting from treatments applied throughout the life of the plant to treatments applied at certain stages of growth. In general, it has been found that abundant water supply increases the quality of foliage of most vegetable plants and also increases the yield of saleable material. It seems clear that each crop will have to be considered on its merits regarding irrigation requirements. Work has continued on the development of an irrigation gauge.

The Entomology Section has made further studies on beetle predators of the cabbage root fly. It was confirmed that low rates of soil insecticides broadcast on the soil resulted in an increased infestation of cabbage root fly. Further work is being carried out on the soil application of soil insecticides for control of carrot fly on carrots and parsnips. An outstanding result obtained by the Pathology Section was the successful use of zinc frit for control of the crook root disease of watercress, resulting in increased yield. Weed investigations include observations on the effect of vegetable cropping on the weed population of original corn land. Various herbicide trials are also in progress. The Statistics Section has, besides handling routine inquiries from other Sections, investigated fitting of growth curves and has worked out designs for the assay of virus preparations on *Nicotiana glutinosa* and *Phaseolus vulgaris*. Apart from the usual weather observations, the use of a special rain-gauge with its rim only 1 in. above ground was continued. Rainfall collected in this gauge was 5 per cent greater than that collected in the standard gauge, thus confirming previous observations at this Station. By using gauges at different heights above the ground it was found that the amount of rain collected was a function of the height of the gauge above the ground and the run of the wind.

METALS AND ALLOYS ABOVE 1,200° C.

A SYMPOSIUM on "The Study of Metals and Alloys above 1,200° C." was held in the Department of Metallurgy of the University of Oxford on September 17 and 18; the subjects discussed at the four sessions are outlined below. Prof. W. Hume-Rothery welcomed the visitors to the symposium in an introductory address, and emphasized the increasing importance of the topic under discussion. He urged that metallurgists should look ahead five or ten years: design engineers were always limited by the high-temperature alloys available to them.

Metals and Alloys of High Melting-point

The first session was devoted to a study of the properties of some refractory metals and alloys—the platinum metals, tungsten alloys, molybdenum, and titanium–carbon alloys. Prof. E. Raub (Forschungsinstitut für Edelmetalle und Metallchemie) emphasized the relatively high reactivity with gases and refractory materials possessed by the platinum metals and alloys at high temperatures. Subsequent discussion centred on whether oxygen diffusion can take place through platinum, and it was concluded that it did not diffuse through metal of very high purity, although internal oxidation, for example, has been observed in dilute alloys. Raub also considered the reaction of the platinum metals with refractory materials, and described methods of melting and annealing these alloys, pointing out the main difficulties encountered by metallurgists studying their behaviour.

R. Kieffer, K. Sedlatschek and H. Braun (Metallwork Plansee, Reutte-Tirol) presented a paper on sintered high-melting tungsten alloys, outlining various methods for preparing the metal and for the production of cold ductile alloys. The alloy systems described were tungsten–molybdenum, tungsten–niobium and tungsten–tantalum; in the last case the following properties of sintered tungsten alloys with 0–100 per cent tantalum were outlined: density, hardness, elastic moduli, electrical resistivity, ease of hydrogenation, oxidation behaviour and corrosion resistance in acids and alkalis.

A. R. Moss (Armaments Research and Development Establishment, Woolwich) considered the thermal, mechanical and physical factors affecting the grain structure of arc-melted molybdenum, and finally R. L. Bickerdike and G. Hughes (Royal Aircraft Establishment, Farnborough) described a vacuum-quenching furnace which had been used to examine the titanium-rich end of the titanium–carbon system between 1,558° C. and 1,763° C.

High-temperature Techniques

The session opened with papers on zone melting by G. A. Geach and F. O. Jones (Associated Electrical Industries) and J. A. Belk (Woolwich). The first paper described an arc-melting technique and also a floating-zone method, using electron-bombardment heating to melt a narrow zone of the specimen, applied to refractory metals including rhenium and tungsten. Belk gave further details of the latter method, applied to the removal of carbon from vacuum-cast molybdenum. The mechanical properties of the purified material in single crystal and polycrystalline form were summarized.

Arc-melting processes were outlined in papers by A. R. Moss (Woolwich), J. R. Murray and G. K. Williamson (Atomic Energy Research Establishment, Harwell) and F. O. Jones, A. G. Knapton and J. Saville (Associated Electrical Industries). Moss discussed the basic principles of the various vacuum-arc and inert-gas arc-melting processes, followed by a consideration of the electrical and mechanical equipment in common use. Murray and Williamson reviewed the application of arc-melting, and other melting techniques used in alloy investigations at temperatures above 1,200° C. at Harwell, and further descriptions of arc-furnace techniques were given by Jones, Knapton and Savill, who also considered electron bombardment heating as supplementary to arc-furnace techniques. Finally, a special molybdenum-wound cooling curve furnace was described by W. Oldfield (British Cast Iron Research Association), in which the element completely surrounds the specimen container.

Physical Properties and Equilibria at High Temperatures

The first two papers were concerned with crystal structure. A. J. Martin and A. Moore (Atomic Weapons Research Establishment, Aldermaston) discussed the structure of beryllium at temperatures between −185° C. and 1,290° C. No evidence was found to support other workers' claims of allotropy in the range 400–800° C. They showed, however, that the lattice is hexagonal up to about 1,250° C., above which the structure is body-centred cubic, and the authors discussed the possibilities of retaining this structure form at temperatures below 1,250° C.

The Metallurgy Department, Royal Aircraft Establishment, Farnborough, then presented a paper on the structures of graphites deposited from hydrocarbon gases at various temperatures and pressures. The effect of changes in deposition temperature on the density and X-ray diffraction pattern was shown. 'Flecks', not unlike deformation bands, are produced on the surface of these graphites when they are deformed.

The remaining papers of the session were concerned with high-temperature equilibria; C. W. Haworth (University of Oxford) described tungsten-resistor furnaces in which specimens weighing 1–5 gm. can be annealed *in vacuo* or in argon up to 2,700° C. and then quenched. The apparatus has been used in work on molybdenum base alloys. A. Hellawell (University of Oxford) directed attention to the face-centred cubic/body-centred cubic transition found in the metals of the first three transition series, and described apparatus which has been used in the thermal analysis of these phase transitions. The influence of various solute elements upon the transition in manganese and iron was shown to be related to the structures of the elements concerned.

The last paper of the session, by P. Gross, D. L. Levi and G. Wilson (Fulmer Research Institute), discussed methods for determining the thermodynamic activities of alloy constituents at high temperatures. Two methods for measuring vapour or reaction pressures have been used—an effusion method (restricted to systems in which the pressure of any constituent does not exceed about 0·1 mm. mercury) applied to alloys containing iron and aluminium at 1,300° C., and also a capillary vessel method where the reaction pressures are beyond the range of the effusion method.

Mechanical Properties at High Temperatures

In a paper on high-temperature mechanical working of molybdenum, E. W. Ward (Woolwich) discussed the factors affecting the breakdown of the arc-cast structure. The microstructures produced by rolling and extruding at temperatures up to 1,800° C. showed that true hot working had been achieved.

Two papers concerned with the measurement of mechanical properties followed. L. M. T. Hopkins (National Physical Laboratory) described determinations of the creep properties of ceramics and high melting-point metals in air and *in vacuo*, respectively. B. L. Mordike and L. M. Fitzgerald (University of Cambridge) are investigating the properties of the refractory metals tantalum, tungsten, niobium and molybdenum, and the carbides of tantalum, tungsten, niobium, titanium, zirconium, vanadium and boron up to their melting points, which lie in the range 2,500–3,500° C. Apparatus to measure the tensile strength of metals, friction of carbides and hardness determinations of metals and carbides were described.

D. M. Gilbey (Farnborough) presented an extension of the simple theory of the thermal stresses in flat plates, so that variations with temperature and stress of the thermal and elastic properties of the material can be taken into account. The stresses calculated by this method for a manufactured graphite were compared with those obtained from the simple theory using constant 'effective values' of the 'constants'.

The session concluded with a paper by D. T. Livey (Harwell) on the high-temperature stability of oxides and sulphides. The behaviour of the stable refractory oxides *in vacuo*, oxidizing and reducing atmospheres was considered; the refractory sulphides are thermodynamically less stable, in general, than the oxides, although the sulphides of cerium and thorium have been used for reactive metals. Kinetic factors, rather than thermodynamic stability, control the degree of reaction between metals and oxides or sulphides, at least for the more reactive metals.

During the symposium, an exhibition of apparatus, refractories, etc., was held at the University Department of Metallurgy. Exhibits were lent by a number of industrial firms, research establishments, and university departments.

J. W. MARTIN

INVASIVENESS AND SURFACE PROPERTIES OF CANCER CELLS

An informal symposium on the surface properties of cells and their possible bearing on the invasive movements of cancer cells was held at the Chester Beatty Research Institute on July 4. The chair at the morning session was taken by Prof. A. Haddow and in later sessions by Dr. B. Sylvén (Stockholm) and Prof. G. Klein (Stockholm).

Prof. Haddow pointed out in his introductory remarks that the bearing of the surface properties of cancer cells on their invasiveness has received little attention, apart from the microhistological studies of Dr. Coman and his collaborators in the United States. But interest in the surface properties of cancer cells has developed during the past few years, stimulated largely by Dr. M. Abercrombie's studies of cell movements in tissue culture. It had, therefore, been decided to bring together some of those specialists most directly concerned with this largely unexplored field.

Dr. M. Abercrombie (London) then described the conditions for the invasion of normal cell explants by tumour cells in culture. Whether or not invasion occurs appears to be determined largely by the effect that contact between interacting cells has on their locomotion. In the cell species so far studied, it is found that sarcoma cells invade explants of normal fibroblasts, whereas populations of normal fibroblasts do not invade each other. Sarcoma cells invade because they treat normal fibroblasts like any other substrate for their locomotion. They adhere to and are guided by oriented structure in any substrate, whether cellular or non-cellular.

To a normal fibroblast other fibroblasts are not simply equivalent to substrates ; they are obstacles to locomotion. Contact with them results in an adhesion, immobilizing the small-scale membrane activity in its neighbourhood and stopping the cell from advancing in the direction of the adhesion. This is contact inhibition (Abercrombie and Heaysman, 1954 ; Abercrombie and Ambrose, 1958). Its nature is unknown, but it is possible to reduce it by changing the composition of the liquid phase of the culture (Curtis, unpublished). The behaviour of fibroblasts towards sarcoma cells appears to be different from the behaviour of sarcoma cells to fibroblasts. There is some inhibition of fibroblast locomotion by sarcoma cells which seems to be effected through a diffusible agent. A small number of experiments have shown that explants of sarcoma cells of different type invade each other.

Is it possible that the loss of contact inhibition and increased activity of the cell membrane is related to the uncontrolled growth of tumours ? Prof. M. Swann (Edinburgh) described some interesting observations on the growth of soil amœbæ, which suggest that in this organism growth is affected by contacts. Mr. D. Harrison, working in Edinburgh, had studied the growth of *Hartmanella* in sterile culture. Growth in this case appears to be limited by mutual contact, which is reflected, after an early exponential phase, in the fact that the growth-curve of an amœba culture becomes linear over a considerable range, before it finally flattens out. A variety of experiments have shown that this is not due to environmental conditions, but solely to cell contacts. The linear phase can be abolished by treatment with antisera, when the growth-curve remains exponential for much longer. It seems possible that the contact effect is a direct mechanical inhibition of vacuole intake. Treatment with antiserum presumably prevents close contact and so abolishes the inhibition of growth by contact. Although experimentally difficult to carry out, a similar investigation using mammalian cells would be of great interest.

Various physico-chemical techniques are now being used for a direct study of the nature of the cell surface ; they were described by Dr. G. C. Easty (London). He first referred to earlier work on the erythrocyte membrane, which indicates that it is of a lipoprotein nature. A direct examination of the membrane is more difficult with mammalian cells, but it is known that tumour cells carry a net negative electrical surface charge which is almost twice that of the homologous normal cells (Ambrose, James and Lowick). Further information has been obtained by G. C. Easty, D. M. Easty and E. J. Ambrose, who have studied the effect of enzymes upon the adhesiveness of tumour cells to glass surfaces by a new centrifugation technique. The most effective enzymes for breaking contacts between ascites tumour cells and glass have proved to be lipase, phosphatases and elastase. These enzymes are thought to react with lipid, phosphate groups and protein, suggesting that the tumour cell surface is also composed of lipoprotein. The increased negative electrical charge could, therefore, be due to an excess of phosphate groups of phospholipid.

A more general biological approach to the changes in cell populations arising during transformation from normal to tumour tissue was then considered by Prof. and Mrs. G. Klein (Stockholm). They have obtained most interesting evidence for a progressive transformation in sublines derived by selective transplantation from a single tumour (*MCIM* sarcoma). The M_{SS} sublines are solid tumours which do not readily produce ascites cells when transferred to the peritoneum, and only produce metastases very late in the growth of the tumour. The M_{AS} sublines readily form ascites tumours and produce early metastases. These stepwise changes in biological characteristics can be correlated quite well with surface changes, the more anaplastic cell types (M_{AS}) showing a higher electrical charge than the M_{SS} types (Purdom, Klein and Ambrose).

Prof. E. Wolff (France) described a valuable technique using organ culture with mixed tissues and mixed species for the study of invasive movements. Real organ chimeras can be produced from associated duck and mouse testes in which testicular tubules may be formed from cells of the mixed species. In fragments of chick and mouse lung also, the mouse bronchial tubes grow and branch in pure chick connective tissue. Sometimes the two epithelia join and form a common canal. These results indicate that homologous tissues of the two species show more mutual affinities than heterologous tissues of the same species. Several sarcomas have been examined under the same conditions by Prof. Wolff. Fusion between embryo and tumour first occurs. All tumours then show a marked tendency to invade a number of organs, such as mesonephros, metanephros, gonad, skin, intestinal coat, lung, liver, etc. Carcinoma cells show a marked tendency to invade similar tissues to sarcomas, although they retain some capacity to proliferate as dense gatherings or secondary nodules.

Direct histological studies of growing tumours were described by Dr. B. Sylvén (Stockholm). With epithelial tissues in both normal regeneration and tumour growth, the connective tissue exhibits the following changes : (1) a general increase in water content ; (2) an increased metachromatic component and (3) appearance of alkaline phosphatase in the ground substance. The extent of the changes gives a measure of the growth-rate and degree of malignancy of the tumour. With normal regeneration, the original connective tissue structure is reversibly restored with cessation of growth. The actual invasion of neighbouring tissues by tumour cells is seen to occur through channels and cavities already present in the normal structures ; in addition, a considerable release of enzymes, particularly proteases, occurs. Such a transformation suggests a primary defect in the organization of the malignant cell membrane leading to increased permeability. Incidentally, malignant cells also show an increased permeability to glucose. Such a penetration of enzymes could remove surface adsorbed protein and account for the decreased adhesiveness and high negative charge of tumour cells.

Prof. K. Setälä (Helsinki) then described some experiments which may give a bearing on the actual mechanism of the cellular transformation which gives rise to the altered properties of tumour cells. He described how a number of surface-active agents of the 'Tween' detergent type can act as powerful promoters in carcinogenesis ; that is, they lead to a marked increase in tumour incidence when combined with a given carcinogen. Electron microscopy of the epidermal cells of the interfollicular areas of a mouse's back indicate that marked changes in cell contacts with intercellular gaps and bridges are produced by the promoting agents. Surface-active agents which do not act as promoters, on the other hand, lead to an actual hindrance of proliferation and increased regions of close contact between the cells.

Dr. E. H. Mercer (London) also described some of the valuable results he has obtained by high-resolution electron microscopy of cell contacts. Electron micrographs of cell membranes (Birbeck and Mercer) indicate that they consist of a layer structure about 60 A. thick which could correspond to the lipid lying between protein layers, as proposed by Prof. J. F. Danielli. The membranes are generally separated by a distance of 150–200 A., suggesting the presence of a cementing material between the cells. Anaplastic tumours often show changes in their cell contacts as compared with normal tissues. They may show a convoluted surface with only small areas of contact; the contacts are more like those of normal cells during the early stages of tissue formation. The electron microscopy, therefore, supports the view that the surface properties of tumour cells are changed in comparison with the normal cells from which they are derived.

In conclusion, mention may be made of two other techniques which are being applied to the problem of cell movements and cell contacts. Dr. H. Harris (Oxford) described a simple but most effective method which he has applied to the study of groups of white blood cells. A long exposure is made with dark-field illumination. On subsequent development of the plate, the paths of the moving cells are recorded as streaks on the photographic emulsion. This technique is particularly useful for the study of a taxis affecting the over-all direction of cell migration.

Finally, Dr. R. J. Goldacre (London) described an approach based on the use of electronic models. In normal growth and maintenance the transfer of information from cell to cell evidently occurs. Direct contacts between the cell membranes appear to play a part in this, at least in the early stages of development. An electronic model consisting of units ('cells') which can stimulate and be stimulated by others can be designed. By connecting the units together in different groups, various complex patterns of interest in morphogenesis are generated in the system; for example, patterns with polarity, discrete differences between neighbouring units, etc. On the basis of such a picture, it would be expected that a small loss of cell – cell interaction, arising from surface changes, could readily lead to abnormal and uncontrolled growth in tumour tissues.

E. J. AMBROSE

PREDICTING ACADEMIC SUCCESS

THE purpose of a recent investigation by Sigvard Rubenowitz, of the Swedish Council for Personnel Administration, Gothenburg, was to determine the weights which have to be assigned to different tests and biographical data in order to predict success in academic studies*. The freshmen at the three universities in Gothenburg in 1954 were invited to take part in the investigation, the results of which would later be related to success at university as measured by examination results. Freshmen were chosen as subjects for the investigation in order to avoid bias in the results of the tests arising from different academic studies. In all, 440, or 62 per cent, of the freshmen responded to the invitation.

After two years, information about examination results was collected and this was related to the data collected two years earlier.

The data collected and the tests which were given to the students were: (1) grades in the matriculation examination; (2) study habit assessments; (3) intelligence test marks; (4) technical test marks; (5) mathematical–technical test marks; (6) organization test marks; (7) details of interests; (8) psychodiagnostic test assessment; and (9) attitude assessment.

Analysis of the results showed that of 43 female students who studied languages and 18 who were studying psychology the validation data in Table 1 were obtained.

It became clear that, for languages, more time is required for study than for other subjects. In addition, a significant correlation exists between intellectual and matriculation results on one hand and success in language studies on the other. The study habit also appears to be of great importance in the study of languages. With psychology, general intelligence, together with those qualities which find expression in a good matriculation result, are not of such decisive importance as are certain mathematical technical aptitudes and some characterological factors that are measured by the Zulliger test.

Table 1

	Languages, 43 students	Psychology, 18 students
Grades in matriculation examination	0·43	0·12
Study habit inventory	0·38	0·17
Intelligence test	0·40	0·28
Technical test	0·17	0·31
Mathematical–technical test	0·06	0·23
Organization test	0·04	0·28
Psychodiagnostic test	0·15	0·37
Attitude assessment (the 'rigid' pole)	0·21	0·25

With certain male students the subject groups that formed the object of the validation were languages. psychology (philosophy), mathematics (statistics) and zoology (botany). The students of mathematics and statistics were, in general, superior to all others and above all in their intelligence and mathematical–technical ability. The male language students, like their female counterparts, made a significantly poor showing in their examination results.

The validation data in Table 2 were obtained from this inquiry.

Comparing these results with those for female students, the same trend is found except in the case of the matriculation result; this was of most value in prognosis for female students of languages, whereas for male students its value is highest for prognosis of psychological studies.

---

* *Occupational Psychology*, 32, No. 3 (July 1958).

Table 2

	Languages, 35 students	Psychology, 15 students	Mathematics, 12 students	Zoology, 10 students
Grades in matriculation examination	0·09	0·53	0·58	0·08
Study habit inventory	0·25	0·14	0·50	0·42
Intelligence test	0·33	0·31	0·82	0·29
Technical test	0·18	0·43	0·47	0·25
Mathematical–technical test	0·22	0·25	0·61	0·06
Organization test	0·34	0·11	−0·04	0·01
Interest blank. (University Arts Faculties Scoring Scheme)	0·06	−0·65	−0·37	−0·30
Interest assessment (Chalmers University Scoring Scheme)		0·49	0·42	
Psychodiagnostic test	0·55	0·62	0·38	0·49
Attitude formula (the 'rigid' pole)	0·17	0·13	−0·08	0·03

At the University of Technology the coefficients of validity in Table 3 were obtained.

It appears that the matriculation examination has a considerably higher prognostic value for these than for those at the University (arts faculties), probably because the courses at the former have to be followed closely and in many respects resemble pre-matriculation studies. For this reason, the matriculation examination can be considered as a job sample test.

A combination of the matriculation results and tests would form the most suitable instrument of prognosis for these students, provided that the multiple regression calculation stands up to cross-validation in a renewed investigation.

Table 3

	219 students
Grades in matriculation examination	0·67
Study habit inventory	0·30
Intelligence test	0·15
Technical test	0·22
Mathematical–technical test	0·32
Organization test	0·09
Interest blank	0·20
Psychodiagnostic test	0·22
Attitude assessment (the 'rigid' pole)	0·01
Entrance qualifications (matriculation grades + previous factory experience)	0·52
Best combination of six prognostic variables	0·77

At the University of Economics the criterion used was the average result in all the subjects passed. The coefficients of validity were as shown in Table 4.

Table 4

	49 students
Grades in matriculation examination	0·22
Study habit inventory	0·46
Intelligence test	0·18
Technical test	0·31
Mathematical–technical test	0·34
Organization test	0·18
Interest blank	0·16
Psychodiagnostic test	0·36
Attitude assessment	−0·04
Best combination of seven prognostic variables	0·77

The study habit inventory had the highest validity here, followed by Zulliger's psychodiagnostic test and the mathematical–technical test. The low validity of the matriculation result is worthy of note.

INDUSTRY AND GOVERNMENT IN CANADA

In his Messel Lecture, "Industry and Government in Canada", before the Society of Chemical Industry at Montreal on September 15, the Rt. Hon. C. D. Howe, P.C., reviews changes in the responsibilities of government and the attitude of industry during the past fifty years. When he came to Canada as a graduate engineer in 1908, Mr. Howe said that most people regarded activities at Ottawa as remote and of very little personal concern. Now, an industrial revolution and relatively sudden highly scientific industrial and military developments, with the rise of the Welfare State, had transformed the scale and character of government administrative responsibility. While the population had grown from 6·5 million to 17 million, government expenditure had multiplied about twenty-five times and was now 5,272 million dollars a year. Mr. Howe believed that most Canadian business men to-day recognized that the public demanded services which only government could provide and that many of them not only tolerated government activity but also were prepared to admit that government action could promote the prosperity and welfare of the country. There had also been a similar improvement in the attitude of government towards business in Canada, and his experience as a Minister during 1935–57 led him to believe that the role of industry and commerce in society was better understood than it had been before.

Mr. Howe then referred to some changes in the administrative structure and notably the appearance of what is known in Canada as the Crown Corporation, on which experienced business men gave part-time service as directors. This pragmatic device, analogous to the public corporation in Britain, had received much more extensive use since 1935, and after noting the establishment of the National Research Council as a Crown Corporation, out of the Advisory Council on Scientific and Industrial Research formed in 1916, Mr. Howe described a few examples including some of the twenty-eight Crown Corporations formed during the Second World War in the Department of Munitions and Supply, of which he became Minister in 1940. During and after the War the Department functioned directly as the sole procurement agency for the three Armed Services, and he thought that the Crown Corporation had proved itself to be an efficient device for enabling government to cope with certain new responsibilities thrust upon it by an advancing technology. Generally, he thought that the government should not enter into any business that is competitive with private industry, but certain responsibilities that could not be directed to private industry and certain other responsibilities which no private industry was prepared to undertake were most efficiently discharged through a Crown Corporation, nor did he think the device need be abandoned if private industry later entered the field. He also thought that the Crown Corporations had made an important contribution to better understanding between government and business, and in his twenty-two years experience it had been amply demonstrated that complete co-operation between government and business is a prerequisite of national prosperity.

A NATIONAL TYPE CULTURE COLLECTION OF MARINE BACTERIA

By Dr. J. M. SHEWAN, G. D. FLOODGATE and P. R. HAYES

Torry Research Station, Aberdeen (Food Investigation Organization, Department of Scientific and Industrial Research)

FOR many years now, work has been proceeding at the Torry Research Station on the bacteriology of marine fish and on the changes in flora occurring during spoilage and processing. It has generally been recognized that the identification of most of the organisms concerned is one of extreme difficulty. It has often been impossible to be sure of the correct family or tribe, let alone the species. These difficulties are not, of course, confined to the microflora of fish; they are also encountered through the whole of marine bacteriology and especially in the *Achromobacter*, *Pseudomonas* and *Vibrio* groups.

A primary handicap has been the disappearance of the type species of many of the genera commonly occurring in marine, soil, air or fresh water environments. Thus, so far as we are aware, authentic cultures of *Achromobacter liquefaciens* and *Flavobacterium aquitale*—the type species of these two genera in Bergey's determinative manual[1]—no longer exist in any type culture collection. Moreover, the descriptions of these organisms in the literature as well as those of many related species are completely inadequate. One example of the confusion that has arisen may be mentioned. Wells and ZoBell[2] in 1932 isolated an organism from the skin lesions in the California killifish and named it *Achromobacter ichthyodermis*. In the original description no mention was made of several features now regarded as essential for taxonomic purposes, for example, type of flagellation and mode of dissimilation of glucose, so that the organism could well be placed in either the *Achromobacter*, *Pseudomonas*, *Aeromonas* or *Vibrio* genera. Indeed, it is classified as a *Pseudomonas* in the 1957 edition of Bergey's manual and as *Achromobacter* by Brisou[3]. In 1950, an organism was isolated at this Station from a lesion in plaice and provisionally classified as a *Pseudomonas* sp., and within the past two years Baage and Baage[4] have isolated a bacterium from lesions in Baltic cod which they believed to be identical with *Vibrio anguillarum*[5], the causative organism of the classical 'red disease' of eels. Recent comparison here of these three organisms has shown that they are closely allied, if not identical, and are probably vibrios. Unfortunately, no authentic culture of *Vibrio anguillarum* appears to be available in any type culture collection, so that the complete identity of these three isolates with *Vibrio anguillarum* must remain in doubt.

It is not surprising, therefore, that investigators frequently state that the bacteria that they have isolated do not fit any description given in Bergey's manual or any other determinative system. Consequently, a multiplicity of species, nomenclatures and taxonomic groupings has arisen. We have recently examined more than 100 cultures, 70 from Scandinavia and 30 from North America and all from marine sources. In only about 30 instances did our taxonomic positioning agree with that of the senders, simply because of the divergence of opinions as to which characters are of taxonomic significance.

It is, of course, recognized that a chief difficulty in classifying bacteria from air, soil and water is that the available diagnostic tests, which arose mainly from the detailed studies of animal and human pathogens, yield almost invariably negative results. It is clear that a much more detailed study of the non-pathogens is required and in particular of the Gram-negative asporogenous rods—the *Achromobacter*, *Pseudomonas*, *Flavobacterium* and *Vibrio* groups—to reduce the present chaos to order. New tests of taxonomic significance will have to be found and will only be forthcoming from a thorough study of the biology, physiology and biochemistry of these groups in question.

To begin such a study two essentials at least are required.

(1) The re-isolation and full description of the type species mentioned above, or, where this is impossible, an agreement among taxonomists that a particular organism, known to exist, shall in future be designated the type culture.

(2) The setting up of type culture collections so that cultures are available for comparative purposes: frequently, papers are published that describe apparently new species, none of which has been kept viable or been deposited in a type culture collection.

There appear to be few type culture collections of marine bacteria anywhere outside of the United States. Prof. C. E. ZoBell at the Scripps Institute, La Jolla, California, and Prof. C. E. van Niel at the Hopkins Marine Station, Pacific Grove, California, both maintain small but valuable collections. A few marine strains are held in private collections and at the Pasteur Institute, Paris, and the Microbiological Institute, Delft, and, no doubt, elsewhere. For years the Torry Research Station has maintained a small collection of bacteria mainly from marine fish and solar salts. The need, however, of putting this collection on a more permanent basis and of more detailed studies of the various groups, with the view of better taxonomy, has now been recognized. Marine bacteria play an important part not only in fish spoilage but also in the deterioration of submerged materials, nets, seaweeds, as well as in the biological cycles in the sea. As a result of consultations between various Government Departments, the Development Commission and the University of Aberdeen, funds and personnel have been made available for broadening the basis of the collection held at Torry so as to include bacteria from all marine sources and for a start to be made on more detailed studies of certain selected groups. The present collection, which will form one of the British national collection of type cultures, comprises some 200 named strains of marine bacteria in addition to several hundred recently isolated unnamed strains. All these organisms are at present maintained on culture media and work is now proceeding to test the best method for their long-term preservation.

The collection, though small, is already becoming known to many research workers. Last year more than 100 cultures were sent to laboratories all over the world, but it will take some time to develop it and to prepare a catalogue.

Meantime, bacteriologists are invited to deposit cultures of marine bacteria in the collection, particularly so that their isolates may not be lost but be made available for future comparison. In this way it is hoped that some measure of progress may be made in establishing, on more solid foundations than hitherto, the taxonomy of marine bacteria.

SOME NEW NEUROMUSCULAR BLOCKING AGENTS

By Dr. H. O. J. COLLIER*, J. M. Z. GLADYCH, BARBARA MACAULEY†
and Dr. E. P. TAYLOR

Research Division, Allen and Hanburys, Ltd., Ware, Herts

FOR muscular relaxation in anæsthesia, suxamethonium has the advantage of brevity of action but the disadvantage of possessing no satisfactory antagonist and of sometimes causing post-operative muscle pains and stiffness[1]. Laudexium (laudolissin)[2] is antagonized by neostigmine and does not, so far as we know, cause muscle pains, but it is of longer duration of action than suxamethonium. It occurred to us that it might be possible to prepare an agent combining the valuable properties of both compounds by incorporating some of the chemical features of each into one molecule.

Three series of compounds were investigated. *Type I : Symmetrical bis-esters.* These were prepared by (*a*) the quaternization of N-alkyltetrahydropapaverines with a suitable ω-bromoalkyl ester or (*b*) the reaction of tetrahydropapaverine with an ω-bromoalkyl ester, and quaternization of the resulting bis-tertiary amine with an alkyl halide or sulphate. *Type II : Unsymmetrical mono-esters,* which were obtained from the dialkylaminoalkyl esters of ω-bromo-aliphatic carboxylic acids by quaternization with an alkyl halide, and subsequent treatment of the product with an N-alkyltetrahydropapaverine. *Type III : Symmetrical bis-amides.* The reaction of dicarboxylic acid chlorides with excess ethyleneimine yielded bis-amides of structure :

$$Cl—(CH_2)_2—NH—CO—(CH_2)_n—CO—NH—(CH_2)_2Cl$$

which, after conversion to the corresponding di-iododerivatives, were then quaternized with N-alkyltetrahydropapaverines to yield the required products. The use of phosgene instead of a dicarboxylic acid chloride resulted in the corresponding urea derivatives (IV).

All compounds were examined by intravenous administration to cats, maintained by artificial ventilation and prepared for recording arterial blood pressure and the isometric twitch of the tibialis anterior muscle in response to stimulation of its motor nerve, as described by Paton and Zaimis[3]. The potencies and durations of the neuromuscular blocking actions of the new compounds were compared with those of suxamethonium chloride, or occasionally of (+)-tubocurarine chloride or laudexium methosulphate. Neostigmine methosulphate was given in antagonism tests on some of the new compounds studied. All doses are expressed as weights of salts.

In order to establish norms of potency and duration all doses of the three reference compounds that caused more than 74 and less than 100 per cent depression of the tibialis twitch in all experiments between June 1951 and June 1956 were pooled to obtain overall mean values. These showed that the ratio of potencies in the cat of suxamethonium : (+)-tubocurarine : laudexium was 1·0 : 0·16 : 0·28, and the corresponding ratio of durations was 1·0 : 4·6 : 4·0. Laudexium did not differ significantly from (+)-tubo-

curarine in duration, although, in an initial more limited series of experiments published previously, it appeared to be longer in duration[4].

The results obtained in the cat with the new compounds described above are illustrated in Fig. 1 and summarized in Table 1, from which it will be seen that the only compound more potent than suxamethonium was the unsymmetrical mono-ester, No. 43, and the only compound briefer than suxamethonium was the symmetrical *bis*-ester, No. 41.

Compound 43 was about seven times as active as suxamethonium. It was of long duration of action and did not show antagonism by neostigmine. It was given to one cat at a dose of 500 μgm./kgm. (that is, about 50 times a fully effective dose). Blood pressure fell to about 82 per cent and then rose to about 150 per cent of its value before treatment; the cat survived for 1 hr., and was then destroyed.

Compound 41, although relatively weak, was antagonized by neostigmine in the cat. The cumulative actions of suxamethonium and compound 41 were compared in three cats, in which series of successive equal doses of one substance were given at equal intervals of time. In these experiments, later doses of compound 41 did not last longer in effect than the initial dose, but later doses of suxamethonium were both more long-acting and more effective than the earlier. Table 2 illustrates this finding in one such experiment.

One cat received 20 mgm./kgm. compound 41, which was about six times a fully effective dose. This caused a complete neuromuscular block lasting 34 min. to 75 per cent recovery. There was a 43 per cent fall in blood pressure. At 2¾ hr. after this dose, the cat was alive; a dose of 40 mgm./kgm. then caused a further fall in blood pressure and the cat died.

In conclusion, a search for neuromuscular blocking agents resembling (+)-tubocurarine in mode of action, but briefer in duration, resulted in the

synthesis of three series of bis-quaternary ammonium salts, all possessing structural features in common with laudexium and suxamethonium.

The only compound more active than suxamethonium in the cat was the unsymmetrical mono-ester, No. 43, which was about seven times as active as the reference compound and appears to be one of the most powerful synthetic neuromuscular blocking agents known. It was of long duration of action and did not show antagonism by neostigmine. Cats maintained by artificial ventilation tolerated very large doses.

The only compound briefer in action than suxamethonium was the symmetrical bis-ester, No. 41, which was of relatively low potency. It was not hypotensive at fully effective doses, but relatively large doses caused falls in blood pressure. It was not cumulative when given in repeated doses, and was antagonized by neostigmine in the cat.

This article represents the substance of a communication to the eleventh Congress of the Italian Society of Anæsthesiology, held in Venice on September 12–15. Full chemical and pharmacological details will be published elsewhere. We wish to thank Dr. J. G. Bourne and Mr. G. M. Timmis for helpful discussions, Mr. R. T. Brittain for some experimental contributions, and Mrs. E. Nield and Mr. I. J. Gibson for technical assistance. We are also indebted to the Directors of Allen and Hanburys, Ltd., for permission to publish this work.

HISTOCHEMICAL CHANGES IN KIDNEYS AND ADRENALS OF RATS MADE HYPERTENSIVE BY THE GOLDBLATT METHOD

By Dr. ANTONIO PASQUALINO
Istituto di Semeiotica Chirurgica, University of Palermo, Italy
AND
Prof. GEOFFREY H. BOURNE
Department of Anatomy, Emory University, Atlanta 22, Georgia

GOLDBLATT and his colleagues[1] showed that partial constriction of the renal artery and removal of the opposite kidney induces persistent hypertension. In the dog and rabbit, hypertension is transient unless the opposite kidney is removed, but in the rat[2,3] persistent hypertension occurs after constriction of one renal artery without contralateral nephrectomy. In such animals hypertensive vascular lesions, similar to those found in malignant hypertension in man, develop in the opposite or 'untouched' kidney but are never found in the kidney with renal artery constriction (the 'clipped' kidney). Floyer[4,5] demonstrated that in rats with hypertension of several weeks duration, produced by renal artery constriction and before vascular lesions had developed in the contra-lateral kidney, removal of the clipped kidney restored the blood pressure to normal in a few hours, but the removal of both kidneys had no effects. Since denervation experiments have no effect upon this experiment, Floyer[4,5] suggested that the clipped kidney secreted a substance (renin ?) which altered the blood pressure regulating function of the untouched contra-lateral kidney. Since adrenalectomy abolishes hypertension the adrenals presumably are part of the pressor mechanism which comes into operation when the kidney is rendered abnormal by clipping.

A variety of histochemical techniques were applied to both kidneys and adrenals of rats on which partial renal artery constriction had been carried out by the method of Wilson and Byrom[2]. Some animals were subjected to exactly the same procedure as above but using larger clips which simply hung as a loose collar around the artery and did not compress it at all—this did not give rise to hypertension but caused some decrease of succinic dehydrogenase reaction. The following histochemical reactions were studied at varying times following these two types of ligation (clipping) : succinic dehydrogenase, acid and alkaline phosphatase, 5-nucleotidase, simple esterase, lipid, cholesterol and periodic acid Schiff-positive sub-

Table 1

	Acute animals	Chronic animals
Succinic dehydrogenase	In clipped kidney decrease within 2 days, persisting to 8 days	Clipped kidney normal. Contra-lateral kidney almost normal but negative in patches
Phosphatases Alkaline phosphatase Acid phosphatase 5-Nucleotidase	Reduction of all three phosphatases, greatest in clipped kidneys. Alkaline phosphatase normal by 8 days. 5-Nucleotidase normal by 18 days. Acid phosphatase still decreased at 18 days	All three phosphatases decreased in contra-lateral kidneys. Almost normal in clipped kidneys
Simple esterase	Increased in both kidneys	Decreased in both kidneys
Lipids and cholesterol	Accumulation of lipid in glomeruli of both kidneys at 2 hr. Later accumulation in groups of tubules most obvious in contra-lateral kidney. No cholesterol demonstrated	Tubular lipid only in clipped kidneys. Contra-lateral kidney shows lipid and cholesterol in glomeruli

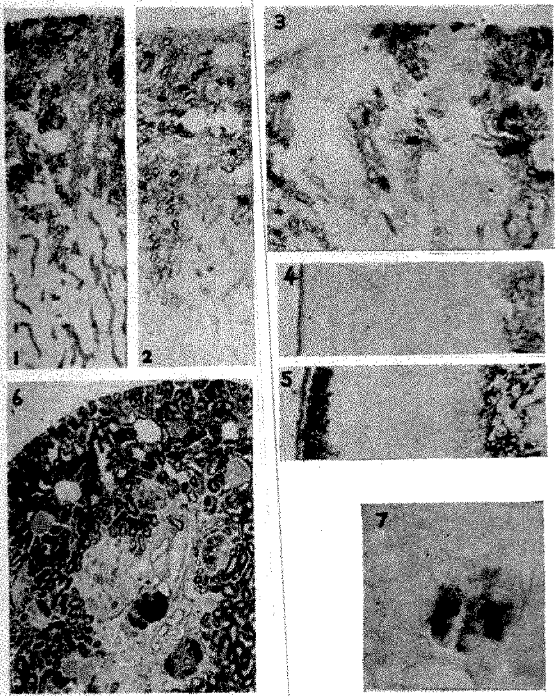

Fig. 1. Succinic dehydrogenase reaction in normal rat kidney. 2, Succinic dehydrogenase reaction in rat kidney (clipped side) with partial clipping of renal artery for five days. Greatly reduced reaction. 3, Succinic dehydrogenase reaction in contra-lateral kidney of rat with renal artery of opposite kidney partly clipped for two months. Reaction almost negative in parts, normal in some patches. 4, 5-Nucleotidase in adrenal of normal rat. Reaction is restricted to the capsule, the narrow zona glomerulosa and the medulla. 5, 5-Nucleotidase in adrenal of rat with one kidney partly clipped for two months. Great increase in zona glomerulosa and in 5-nucleotidase reaction in glomerulosa and medulla. 6, Sudan black (lipid) preparation of contra-lateral kidney of rat with renal artery of opposite kidney partly clipped for two months. Note accumulation of lipid in tubules and in glomeruli. 7, Same animal as in Fig. 6. Schultz cholesterol preparation. A single glomerulus showing accumulation of cholesterol

stances. 'Acute' animals in this account means those animals which have been clipped for periods up to a few weeks and showed no hypertension. 'Chronic' refers to those animals which had been clipped for some months and had developed hypertension. The results are shown in Table 1.

In all animals from 2 days on there was an increase in the width of the zona glomerulosa of the adrenals (said to produce the hormones responsible for electrolyte regulation) accompanied by an increased 5-nucleotidase reaction. There was a decrease of alkaline and acid phosphatase in the cortical sinusoids in the acute animals, and an increase of acid phosphatase in the chronic animals.

Light clipping of one renal artery thus produces changes in activity and distribution of enzymes and accumulation of lipid in both kidneys within two hours. More profound changes occur in both kidneys and adrenals within two days. Within three weeks most, but not all, of these changes have returned to normal in the clipped kidneys. In the contra-lateral kidneys some changes persist into the chronic stage and presumably play a part in the development of pathological changes there. The changes in the adrenals persisted or increased in chronic (hypertensive) animals. Attention should be directed to the accumulation of cholesterol in the glomeruli of the contra-lateral kidney in chronic animals, to the fact that the histochemical changes occur very quickly and precede both pathological changes and hypertension and to the fact that even placing a clip in position around the renal artery without any compression at all causes changes in the succinic dehydrogenase activity of the clipped kidney.

The cause of these changes is not yet established; but their existence must lead to speculation as to whether the renal artery itself, in response to irritation, is not capable of secreting a substance which, by affecting the clipped kidney, causes the whole cycle of events which lead to the initiation of hypertension.

This work was assisted by a grant from the Medical Research Council to Dr. A. Pasqualino. We are greatly indebted to Dr. M. A. Floyer of the Medical Unit, The London Hospital, Whitechapel, for the provision of clipped rats for this work and for much helpful comment and details of literature.

MELANIN: A NATURALLY OCCURRING CATION EXCHANGE MATERIAL

By Dr. LAURENS P. WHITE

Department of Medicine, Stanford University School of Medicine, San Francisco, California

It is the purpose of this report to present results which demonstrate that melanin from two different sources has strong cation exchange activity.

Although melanin is a substance of immense sociological and physiological significance, little is known of its structure, reactivity, physical state, or of the functions which it may possess. Greenstein[1], Mason[2] and others[3] have characterized the elementary composition, some precursors and certain physical facts about some plant and animal melanins. Commoner *et al.*[4] have shown that melanin contains stable free radicals, and have commented on the chemical significance of this fact.

It has become generally accepted that melanins are complex polymeric substances intimately bound to protein. *In vivo*, melanin is thought to exist as particles of 0·1–1·0μ diameter. Crude preparations of melanin granules are completely insoluble in water and all common organic solvents; the granules are soluble in hot aqueous sodium hydroxide, in which melanin probably undergoes depolymerization; melanin is apparently soluble in dilute sodium carbonate[1]. Dried preparations of granules take up 2–4 times their weight in water. These physical characteristics: complex polymeric structure (thought to be derived from phenolic precursors), insoluble particulate state, Table 1. 8·13 GM. OF DRY MELANIN PARTICLES

Supernatant	Volume ml.	*p*H	Sodium m.equiv./l.	Sodium m.equiv.	Chloride m.equiv./l.	Chloride m.equiv.

and the ability to take up large amounts of water are strongly reminiscent of some of the chief characteristics of synthetic organic ion exchange resins[5]. Therefore, the ion exchange activity of partially purified melanin was examined.

The sources of the melanin used in the following experiments were the transplantable Harding–Passey tumour of mice, taken after eight weeks of growth in *C57/dba* hybrids, and the ink from the ink sac of the Pacific coast squid (*Loligo opalescens*). The tumour (657 gm.) was homogenized in dilute sodium chloride solution and the granules separated by high-speed centrifugation, as described by duBuy *et al.*[6]. The granules obtained were uniform in colour, size and shape. From the starting weight of tumour, 28 gm. of wet melanin granules were obtained. On drying over calcium chloride *in vacuo* a final yield of 13·0 gm. of coal-black lumps was obtained. Squid ink granules were obtained by repeated washing of the particles with water, and high-speed centrifugal separation. The very small particle size of both preparations prevented the use of columns or conventional filters. The washed granules were incubated with dilute saline, washed further and then treated with 0·1 *N* hydrochloric acid. Further centrifugation gave the hydrochloric acid supernatant. All these centrifugal supernatants were collected separately, the *p*H was measured, and the sodium ion content measured. The *p*H of the granules treated with hydrochloric acid was then adjusted to 7·9, the granules washed, treated again with sodium chloride, washed further, and then incubated with hydroxyl, formate or acetate. The *p*H and chloride ion content of each supernatant were measured.

A similar study was performed with aqueous eosin, in which granules were incubated with the eosin solution at neutral *p*H, then washed until the supernatant was free of eosin, treated with 0·1 *N* hydrochloric acid, and the eosin content of the hydrochloric acid supernatant measured.

Table 1 gives a résumé of results in a typical experiment. Incubation of washed melanin granules with sodium chloride appeared to decrease the sodium ion content of the supernatant fluid. Most of this 'lost' sodium ion content reappeared on further washing of the granules, and probably had been retained in the interstices of the granules. Hydrochloric acid, however, eluted a very considerable amount of sodium ion from the melanin with a marked drop in *p*H. It should be emphasized that the amount of sodium ion content found in the supernatant may represent only about half of that actually eluted, for approximately 20 ml. of fluid remained with the granules after each centrifugation.

The results with anions were equally uniform. Regardless of the eluting anion employed, it was not possible to demonstrate anion elution from melanin.

Similar experiments using eosin gave corroboratory results. At neutral *p*H incubation of melanin granules with aqueous eosin markedly decreased the optical density of the eosin solution. After repeated washing of the melanin granules with water, until no absorption at 515 mμ was present in the supernatant, the granules were treated with 0·1 *N* hydrochloric acid. The optical density of the hydrochloric acid supernatant was considerably higher than that of the wash solutions, despite further dilution of eosin. (Treatment with hydrochloric acid of melanin particles not incubated with eosin did not produce any material in the supernatant absorbing at 515 mμ.)

The cation exchange activity of squid melanin was similar to that of mammalian melanin. Squid melanin particles appeared to have a higher level of cation-exchange activity than did the mammalian particles; but this may be due to the greater contamination of the latter.

The results of these experiments indicate that melanin granules from both a mammalian and an invertebrate source have the capacity to act as cation-exchange materials of considerable activity. Bersin[7], who has discussed naturally occurring cation exchangers in man, includes tyrosinase, ceruloplasmin, ascorbic acid oxidase and transferrin. To this short list melanin can be added.

The significance of this cation-exchange activity of melanin in relation to function is speculative, but of great interest. Cassidy[8] has shown that some cation exchange polymers can also absorb electrons. The distribution of melanin in normal animals in areas exposed to light, and its increase in the skin after exposure to sunlight or ionizing radiation make for interesting speculations as to the importance of the ion-exchange activity of melanin as one of its more important functions.

This work was supported by a grant (*CY* 2914) from the National Cancer Institute, National Institutes of Health, Bethesda, Maryland.

INCORPORATION OF CARBON-14 DIOXIDE INTO SUGARS BY DARKENED COTYLEDONS FROM ETIOLATED SUNFLOWER SEEDLINGS

By Dr. CLIVE BRADBEER*

Botany Department, King's College, Newcastle upon Tyne

THE consumption of fat and the concomitant production of sugars by germinating sunflower seedlings have long been known, and low respiratory quotient values have been observed to accompany these changes. Recent experiments[1] with etiolated sunflower seedlings have shown that the acids of the tricarboxylic acid cycle also accumulate during germination. One possible explanation of these facts is that fixation of carbon dioxide in the β-carboxylation of pyruvate or phosphoenol pyruvate to yield oxalacetate or malate contributes to this accumulation, as happens when low respiratory quotient values accompany malic acid accumulation in darkened *Kalanchoë* leaves.

Accordingly, carbon-14 dioxide was fed to darkened cotyledons (usually 2–6 gm. fresh weight), which were cut from 5-day-old sunflower seedlings which had been grown in the dark at 20° C. The darkened vessels containing the tissue were flushed with air free from carbon dioxide for 1 hr. before the introduction of the carbon-14 dioxide. After exposure to carbon-14 dioxide (about 0·5 mc.) for periods of 5 sec.–12 hr., the cotyledons were exhaustively extracted with 80 per cent ethanol. Components in this extract were identified by two-dimensional chromatography on Whatman No. 1 paper with *tert.* amyl alcohol/formic acid/water and propanol/ammonia as developing solvents. Amino-acids were also chromatographed separately after fractionation of the ethanolic extract on ion-exchange resins. Radioactive components were detected by radioautography and the carbon-14 content of individual substances was assayed by counting the active areas on the developed chromatograms. Since all experiments were performed on seedlings of the same age, it has been assumed that all these seedlings contained their various constituents in closely similar proportions, and that the comparison of the relative amounts of radioactivity in the individual substances after varying periods of exposure to carbon-14 dioxide is valid. The malic acid and the glucose moiety of sucrose were degraded by procedures based on fermentation by *Lactobacillus arabinosus* and *Leuconostoc mesenteroides*, respectively.

The most striking result shown in Table 1 is that in experimental periods longer than 5 min. sucrose was the most heavily labelled compound. In earlier work on other tissues fed with carbon-14 dioxide in the dark the free sugars were either unlabelled or possessed only weak activity[2–4]. Even in *Kalanchoë*, which possess exceptionally high powers of dark fixation of carbon dioxide, no labelled sugars have been detected[5].

Table 1. DISTRIBUTION OF CARBON-14 AMONG COMPOUNDS EXTRACTED WITH 80 PER CENT ETHANOL FROM SUNFLOWER COTYLEDONS WHICH HAD BEEN EXPOSED TO CARBON-14 DIOXIDE IN THE DARK

Substance	Period of dark carbon-14 dioxide fixation			
	5 sec.	45 sec.	5 min.	30 min.
Sucrose	0·0	3·6	294·8	2,242·3
Glucose	0·0	trace	20·5	81·0
Fructose	0·0	trace	19·5	109·8
Malate	48·0	412·3	132·5	242·7
Citrate	0·0	22·1	54·0	105·2
Succinate	trace	31·3	10 0	13·0
Fumarate	1·3	44·5	2·8	5·5
Aspartate	8·5	11·2	41·4	71·9
Glutamate		2·5	1·4	6·0
Alanine	4·5	58·1	26·1	30·8
Serine		0·7	2·4	8·4
Glycine		0·9		
	62·3	587·2	605·4	2,916·6

The results are expressed as c.p.m. × 10^{-3}.

With shorter periods of carbon-14 feeding, the bulk of the radioactivity was in malate and in related acids and amino-acids, suggesting that carbon-14 dioxide was incorporated by a β-carboxylation of pyruvate or phosphoenol pyruvate to give malate either directly or indirectly by way of oxalacetate. The enzyme system catalysing this incorporation is as yet unidentified, though Walker (private communication) has detected malic enzyme in the cotyledons of 5-day-old sunflower seedlings.

Table 2 shows the distribution of carbon-14 within malic acid and the glucose moiety of sucrose isolated from the cotyledons which had been exposed to carbon-14 dioxide for 15 min. in the dark. In the malate the isotope was essentially confined to the carbon atoms of the carboxylic groups, and it is noteworthy that the carbon-14, presumably first incorporated into the β-COOH group, was after 15 min. rapidly appearing in the α-COOH group. The radioactivity in the hexose was largely confined to the central carbon atoms, that is, carbon atoms 3 and 4.

The identification of malate as an early product of carbon-14 dioxide incorporation and the subsequent accumulation of label in sucrose suggest that malate is converted into sucrose. This conversion could occur by way of the reactions of glycolysis in reverse, with malate giving rise to either pyruvate directly or phosphoenol pyruvate via oxalacetate as the first reactions. In either case, the carbon-14 present in the β-COOH of the malate would be released as carbon dioxide. The label in the α-COOH group

Table 2. DISTRIBUTION OF CARBON-14 IN MALIC ACID AND IN THE GLUCOSE MOIETY OF SUCROSE FROM SUNFLOWER COTYLEDONS WHICH HAD BEEN EXPOSED TO CARBON-14 DIOXIDE FOR 15 MIN. IN THE DARK

Glucose		Malic acid	
—CHO	5·2	—COOH	30·5

would be retained in the pyruvate or phosphoenol pyruvate and incorporated as carbon atoms 3 and 4 of the hexoses. Broadly the isotopic distribution reported for the glucose moiety of sucrose in Table 2 provides support for the reactions outlined. Since quantitative physiological studies[1] have demonstrated that, at the same stage of seedling growth, the fatty food reserve in the sunflower cotyledons is being rapidly converted into sucrose, a possible inference is that malate is an intermediate in this fat into carbohydrate conversion.

The glyoxylate cycle of Kornberg and Krebs coupled with a pathway such as that mentioned for the conversion of malate into sugar provides a possible mechanism for the conversion of fat into sugar in sunflower cotyledons. The enzymes relevant to the glyoxylate cycle, shown by Kornberg and Beevers to be present in castor-bean seedlings, have recently been demonstrated in cell-free preparations from the cotyledons of germinating sunflower and peanut seedlings[6]. In addition, feeding experiments with radioactive acetate have provided evidence for the operation of this cycle in the intact cotyledons[6,7]. The operation of the cycle in the cotyledons used in the present experiments could account for the spread of the carbon-14 label from the β-COOH group to the α-COOH group of the malic acid (see Table 2).

The metabolic significance of the incorporation of carbon-14 dioxide into the sunflower cotyledons in the dark is at present unknown. Clearly it may have resulted either from a net uptake of carbon dioxide by the tissue or simply from such incorporation as presumably occurs in any system normally in equilibrium with an atmosphere containing carbon dioxide when carbon-14 dioxide is introduced into that atmosphere. The low respiratory-quotient values (0·5–0·6) which have been observed[1] in 5-day-old sunflower seedlings could result from fixation of carbon dioxide, but can also be explained in terms of the operation of the glyoxylate cycle.

Acknowledgment is due to Prof. M. Thomas and Dr. S. L. Ranson for their helpful guidance and advice, and to King's College, in the University of Durham, for financial support.

EFFECT OF GROWTH SUBSTRATES ON ISOCITRATASE FORMATION BY *PSEUDOMONAS OVALIS* CHESTER

By DR. H. L. KORNBERG, A. M. GOTTO* and PATRICIA LUND

Medical Research Council Cell Metabolism Research Unit, Department of Biochemistry, University of Oxford

ISOCITRATASE, which catalyses the aldol cleavage of isocitrate to succinate and glyoxylate[1–3], is thought to play an essential part in the biosynthesis of cell constituents by micro-organisms growing on acetate as sole carbon source[4–9]. The levels of isocitratase found in bacterial extracts vary widely with the substrate on which the cells are grown[10] (Table 1), suggesting that the enzyme operates only when net formation of C_4-compounds from acetate is necessary for growth. This was tested by incubating a washed suspension of *Pseudomonas ovalis* Chester, which had been grown on acetate as sole carbon source[6], in growth media containing either 50 m*M* acetate or 50 m*M* succinate as carbon sources. Growth of the organisms was followed nephelometrically. At known times, samples of the growing cultures were centrifuged, suspended in 10 ml. of 0·9 per cent potassium chloride, disintegrated by supersonic vibration (at 25 kc./s., generated by a 600 W. Mullard magnetostrictor oscillator at 3·5 amp.) for 2 min., and centrifuged for 15 min. at approximately 20,000*g*. The isocitratase activity of the supernatant solutions was determined by a modification of the method of Olson[11], by measurement in a Cary recording spectrophotometer of the rate of change of optical density at 252 mμ, consequent upon the formation of glyoxylate semicarbazone, when cell extracts were incubated at *p*H 6·0 with semicarbazide and isocitrate.

Table 1. SPECIFIC ACTIVITY OF ISOCITRATASE IN EXTRACTS OF *Pseudomonas ovalis* CHESTER GROWN ON DIFFERENT SUBSTRATES

Growth substrate	Specific activity (μmoles of glyoxylate formed/mgm. protein/hr.) at *p*H 6·0
Acetate	2·78
Glucose	< 0·01
Citrate	0·13
Succinate	0·25
Malate	0·15
Fumarate	0·06
Lactate	0·11
Alanine	0·09
Aspartate	0·08
Glycine	0·14
Glycollate	0·08

Cells used for inoculations of growth media had been maintained on 50 m*M* acetate medium (ref. 6) solidified with 2 per cent agar. Growing cultures were harvested at the approximate mid-point of logarithmic growth and washed with 0·9 per cent potassium chloride. Cell extracts were prepared as described in the text. Isocitratase was estimated spectrophotometrically, by the rate of change of optical density at 252 mμ due to the formation of glyoxylate semicarbazone, in the assay procedure of Olson (ref. 11). The identity with glyoxylate semicarbazone of the material absorbing ultra-violet was confirmed by preparation of the 2,4-dinitrophenylhydrazone from it after the assays, and identification of this derivative by paper chromatography (ref. 13). In all cases, glyoxylate was the only keto compound formed.

The results obtained (Fig. 1) show that these cells grown on acetate contained isocitratase at high specific activity at zero time, and that, when placed in fresh acetate growth medium, the isocitratase continued to be formed at a rate parallel to the formation of cell material. The cells placed in succinate growth medium, which initially contained isocitratase

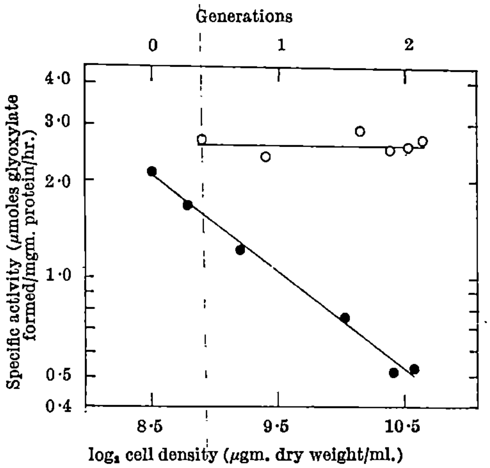

Fig. 1. Variation of specific activity of isocitratase with cell growth. *Pseudomonas ovalis* Chester grown on acetate, incubated in growth media containing 50 m*M* acetate (○—○) or 50 m*M* succinate (●—●) as sole carbon sources

at similar high specific activity, did not continue to form isocitratase, and the specific activity of the enzyme under these conditions of growth fell sharply with increasing cell density (Fig. 1). Under these conditions, the specific activity of the isocitratase decreased by 50 per cent in each cell generation, indicating that the apparent loss of enzyme activity was not due to destruction of the enzyme, but to 'diluting out' during growth.

Cells which had been grown on succinate as sole carbon source initially contained low levels of isocitratase activity (Fig. 2). When such cells were allowed to grow in a medium containing 20 m*M* succinate and 50 m*M* acetate (Fig. 2), the specific activity of the isocitratase remained low and constant despite an increase in the cell density from 0·50 to 1·80 mgm. dry wt./ml. of medium. The plot of the logarithm of cell density against time was linear (mean generation time 1·2 hr.) and showed no evidence of diauxie. Since manometric experiments had shown that cells grown on succinate oxidize acetate without lag, and since the amount of growth observed could not have been supported by 20 m*M* succinate, it must be concluded that the cells were utilizing for growth both the added succinate and acetate simultaneously. Only after the succinate in the medium was exhausted (after a cell increase of two generations) was an increase in the isocitratase level of the cells detected. Cells grown on succinate, placed in 75 m*M* acetate growth medium (Fig. 2), grew only after a lag of approximately 2 hr. During this time, the isocitratase-level rose sharply; the specific activity of the enzyme increased from 0·20 to 1·46 μmoles of glyoxylate formed/mgm. protein/hr. before any growth was detected. By the time the cell density had increased by a third of a generation, the specific activity of 2·7, observed in acetate-grown cells (Fig. 1), had been reached, and was maintained through the subsequent logarithmic growth (mean generation time 1·4 hr.). These results indicate that: (*a*) the formation of isocitratase by *Pseudomonas ovalis* Chester varies with the growth substrates used; (*b*) high levels of isocitratase are formed when a necessity exists for net formation of C_4-compounds from acetate, but the provision of such C_4-compounds in the growth medium represses[12] isocitratase formation; (*c*) the formation of isocitratase precedes growth on acetate. This supports the role of the glyoxylate cycle[4-9] as the route for biosynthesis of cell constituents from acetate; (*d*) isocitratase formation is not induced by acetate in the presence of a C_4-compound. It is possible that it may be elicited by a fall in the intracellular concentration of a repressor[12] (such as an intermediate of the tricarboxylic acid cycle), as would occur with the provision of acetate as sole carbon and energy source.

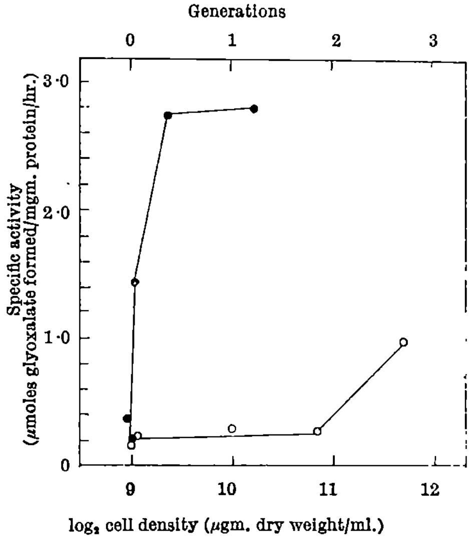

Fig. 2. Variation of specific activity of isocitratase with cell growth. Succinate-grown *Pseudomonas ovalis* Chester incubated in growth media containing 75 m*M* acetate (●—●) or 20 m*M* succinate + 50 m*M* acetate (○—○) as carbon sources

We wish to thank Sir Hans Krebs for his encouragement and interest, Prof. D. D. Woods for the gift of a culture of *Pseudomonas ovalis* Chester, Prof. Boris Magasanik (Harvard Medical School) for many stimulating discussions, Dr. H. B. Vickery (Connecticut Agricultural Experiment Station, New Haven) for a generous gift of potassium dihydrogen L_s-isocitrate, and Dr. June Lascelles for valuable help in the microbiological procedures used. This work was supported by the Rockefeller Foundation and by the Office of Scientific Research of the Air Research and Development Command, U.S. Air Force, through its European Office, under Contract No. *AF*.61(514)–1180.

Carbon-14 Activity during the Past 5,000 Years

RECENTLY, C. Crowe[1] has attempted to demonstrate that the carbon-14 activity in the atmosphere has been subject to considerable variations during the past 5,000 years. He did this by plotting the carbon-14 data of a number of samples of historically known age. By this method a variation in the atmospheric carbon-14 activity appears as a systematic difference between the carbon-14 and the historical age.

On closer inspection the remarkable variations obtained by Crowe are seen to be due to unjustified corrections. In correlating the data of different laboratories, he assumes corrections arising from different recent carbon-14 standards, but the numerical values of these corrections are not realistic. For example, he assumes that the Heidelberg dates are all 375 yr. older, while the Stockholm dates are 525 yr. younger, than those of Groningen. It has been shown previously[2,3] that differences in the recent standards of different laboratories do indeed exist, but the deviations are nothing like so large as Crowe assumes. Laboratories using wood standards from the previous century and others using modern organic material (from about 1930–53) give different ages for the same sample because of the effect of industrial combustion. This has the consequence that modern material and a standard derived from it show a lower activity. The latter group of laboratories accordingly give dates which are too young.

When this effect was discovered by Suess[4], some laboratories already working (for example, Chicago and Groningen) kept their modern standard for the sake of simplicity and intended to ascertain the exact value of the correction before applying it. Thus the Groningen dates are about 240 yr. later than the Heidelberg dates. On the other hand, a large deviation between Stockholm and Heidelberg cannot exist because both laboratories use pre-industrial wood. This has also been established experimentally by dates (unpublished) obtained for the same specimen. It is not quite clear to us how the large corrections found by Crowe arise, but it might be possible that they come from the fact that there are only a few carbon-14 dates of the same specimen made by different laboratories and that some of these dates have large statistical errors. The comparison of such dates will give a 'correction' having a considerable chance deviation, which then will enter the further calculations as a systematic one and seriously affect the results. Indeed, the variations of activity found by Crowe arise essentially from the corrections he applied to the Heidelberg and Stockholm dates, pushing the former up and the latter down. Because of the fact that the Stockholm dates cover the age-range between 1,000 and 3,000 B.P. while the Heidelberg dates are concentrated at 2,000 years ago, a fictitious peak at 2,000 B.P. results.

In Table 1, which corresponds to Crowe's table, tentative values are listed which are to be applied in order to bring the dates of some other stations on to the Groningen scale. The difference between Groningen and Heidelberg dates is experimentally known to some extent by measurements of de Vries[2]. The other laboratories have been provisionally assumed to be equal to Groningen or Heidelberg, depending on the kind of standard they use. Deviations of 1 or at most 2 per cent in activity (up to about 150 yr. in age) are possible but not yet established and accordingly have been disregarded. Using the more realistic and much smaller corrections of Table 1, the data used by Crowe have been replotted in Fig. 1. The large systematic variations indeed vanish. It should be mentioned, however, that the scattering of the points, though much smaller than before, is somewhat larger than to be expected from the root-mean-square counting errors alone. This may be due to the fact that data have been used which do not satisfy the necessary requirements as regards purity and reliability of historical evidence.

Table 1. YEARS TO BE ADDED TO OR SUBTRACTED FROM ALL DATES TO BRING THEM ON TO THE GRONINGEN SCALE, WHICH IS NOT CORRECTED FOR THE SUESS EFFECT

University of Chicago	0
Institute of Archæology	0
Lamont Geological Observatory	−240
University of Michigan	−240
Swedish Geological Survey	−240
University of Heidelberg	−240

Tentative values are given here, the estimated root-mean-square error being ± 80 yr. For the Heidelberg value (−240) the root-mean-square error is smaller (± 40 yr.).

At this stage it can be seen, however, that genuine variations in carbon-14 activity, if present, are almost one order of magnitude smaller than those found by Crowe. In any event, plots of the kind in question will be more reliable as soon as the differences in recent standards are measured more exactly. This is at present being done by measuring standard organic material distributed by the U.S. National Bureau of Standards, Washington, and an artificial standard of higher activity distributed by the Heidelberg labora-

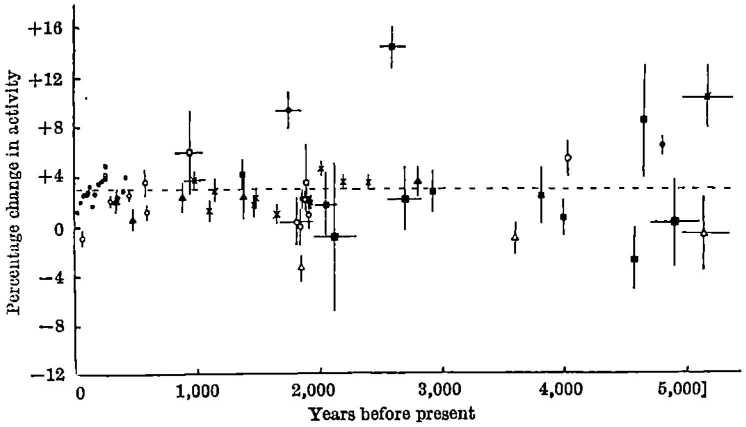

Fig. 1. Change in activity relative to that of the present versus time, taken from Crowe, but with the corrections given in our Table 1. (No attempt has been made to identify or to check the individual points; all points attributed by Crowe to each laboratory have been shifted as a whole.)

[4] Suess, H. E., Proc. Conf. Nuclear Processes in Geologic Settings, Williams Bay, Wisconsin (Sept. 1953); *Science*, **122**, 415 (1955).

IN a recent communication, C. Crowe[1] uses published dates on samples of known age in an attempt to investigate variations of the concentration of carbon-14 in living material during the past 5,000 years. He concludes that the activity has followed a cycle with a maximum change of 10 per cent and with some evidence of a sharp peak of about 10 per cent about 2,000 years ago. His proposed curve is most striking, for the effect, if real, would imply, for example, that all 1,000-year old samples should give radiocarbon ages of more than 1,700 years, a result which has not yet been obtained in practical measurement despite the growing number of accurate measurements on tree rings and other materials of known age.

Crowe assumes in the first place that the observed difference between the radiocarbon age and the known age of a sample is due entirely to the initial carbon-14 activity of the sample being different from that of present living material. This would only be justifiable if all other errors could be shown to have been taken into account, and if the statistical error of the radiocarbon estimation were small compared with the difference between the two ages. This is manifestly not so. Laboratories have differed to some extent in the past in dealing with the errors associated with radiocarbon dating, at first taking into account only the statistical errors of the radioactivity measurements; more recently, as other contributory factors have been discovered (for example, isotopic fractionation effects) these have been taken into account or eliminated when the necessary ancilliary instrumentation was available. Errors arising from the history of the sample before it enters the laboratory or from the lapse of time between the death of the sample and the event being dated are not included, although it is recognized that these effects, which are not amenable to mathematical treatment, may on occasion assume significant proportions compared with the statistical errors.

Secondly, Crowe attempts to eliminate systematic errors by comparing the ages obtained in the cases where laboratories have dated the same sample. This again is open to grave objection on the grounds that there are so few published examples available for such comparisons; no sample is common to all the laboratories mentioned, and in practically all cases the statistical errors are large compared with the observed differences, and thus it is very difficult to understand how his Table 1 was compiled. The only accurate approach to this problem of the elimination of systematic errors is that which is taking place at present and is being sponsored by Dr. K. O. Münnich of Heidelberg, in which all laboratories engaged in radiocarbon research are being asked to make extended measurements on the same homogeneous sample so that statistical and other errors are reduced to a very small value compared with the normal dating error.

Crowe's Table 1 is thus valueless on the above grounds alone, apart from the fact that one finds it difficult, if not impossible, to relate the values he quotes and the estimated error of ± 100 years with the available figures in the publications cited by him.

It is doubly important that the accuracy and validity of these corrections should not be allowed to go unquestioned. In the first place, one must at least attempt to prevent their use by the unsuspecting archæologist, and secondly, it is necessary to point out that Crowe's conclusions regarding the large cyclic variations in carbon-14 activity during the past 5,000 years depend almost entirely on the use of these corrections. Thus, the large depression in the trend line in the range of 1,000–2,300 years is due in the main to the influence of a group of Lamont and Stockholm samples which would occupy a much higher position nearer to the zero line were it not for the very large corrections applied to them by Crowe. Similarly, the evidence of a sharp peak at about 2,000 years seems to rest mainly on the large correction applied to the Heidelberg dates.

A more important point is that de Vries[2] has recently shown that the 'modern' standard in use in Groningen is 3 per cent lower in carbon-14 activity than the average for German trees and that consequently all Gröningen dates are in fact about 240 years too young. Crowe would have us believe that Lamont and Michigan dates are all 400 years younger, and Stockholm dates 525 years younger, than Groningen dates, and that therefore corrections of some 700 and 825 years respectively are required to convert results from these laboratories into calendar years. It is unlikely, to say the least, that three laboratories could be set up independently of each other and pass through the necessary proving and checking phases without detecting discrepancies of this magnitude.

Variations of carbon-14 activity during the past are clearly of importance to radiocarbon dating. It is known that they exist, but certainly at a lower order of magnitude than is implied by Crowe's calculations. The accurate approach to the problem of their evaluation is clearly an extension of the work of Münnich[3] and de Vries[2].

A 'Solid-Image' Microscope

For many purposes, such as tracing networks of neural structure in the brain, a normal microscope has the serious limitation that only a thin layer of the specimen can be studied at one time, owing to the limited depth of focus of microscope objectives. When a thin section is examined, only those structures which happen to lie in the plane of the section can be observed. This plane may be confused by such objects as fibres coming away from or toward the plane of the section. A microscope which gave a large depth of field, and which presented the image as a solid in a luminous block in which the structures could be observed in depth would have important advantages over existing optical microscopes. We have designed and constructed a primitive prototype of an instrument giving such a 'solid image'. It is possible to observe this from any position and to see the structures with appropriate parallax.

The instrument involves two processes. (1) The focal plane of the objective is effectively made to 'scan' up and down through the depth of the section. In the prototype instrument, this occurs at a rate of 50 double scans/sec. The slide is mounted on a steel fork tuned to 50 c./s. which is driven by a polarized solenoid energized by a 50 c./s. sine wave. Thus the slide is carried up and down through the focal plane of the objective 50 times/sec. (2) The image is projected on to a screen mounted on a second tuned fork which vibrates at the same rate and in the same phase as the slide carrying the specimen.

Scanning serves to extract the information in depth from the specimen; the second process reconstitutes it in depth, giving a 'solid image' in the space swept by the screen. Its frequency of vibration is greater than the fusion frequency for the eye, so that little or no flicker is observed.

As the instrument stands at present, the resolution and contrast leave much to be desired. A test slide of human hair does, however, give a fairly satisfactory 'solid image' in which the positions of the hairs may be seen in depth. These positions change as the observer changes his viewing position. If the objective is brought farther from, or closer to, the slide the image of the test hairs moves through the luminous cube in a convincing manner. So far, magnifications greater than 100 have not been attempted, and the greatest useful magnification is only about 20.

We hope to produce an improved version, using the same basic principles but perhaps abandoning the physical screen in favour of shifting the virtual image of viewing lenses. The tuned forks may be replaced by some more precise system for obtaining the 'scanning' oscillatory movements. We intend to modulate the light intensity in order to increase the illumination inside the image. At present the front and back are brighter than the middle, because the velocity of the screen is greater at the centre of its sweep.

It is hoped that an instrument might be developed along these lines which will be useful for biological and other research purposes.

Evidence for $^6_2$He 'Clusters' in Nuclei

The well-known 'α-particle' model of the nucleus, whereby certain low-A nuclei are considered as consisting of groups of α-particles, has recently received a new impetus as a result of work by Wildermuth and Kanellopoulos[1] on the 'cluster model' of nuclei. These authors have presented a formal treatment of the behaviour of 'cluster states' and illustrated it with particular reference to the nucleus $^8_4$Be considered as two α-particle clusters. At the same time they have pointed out that clusters other than $^4_2$He might be present, and in fact suggested that stable closed shells such as those with neutron numbers, N, of 50 and 82, could be considered as large clusters. The question now arises as to which clusters are in fact suitable representations of particular nucleonic configurations, and the purpose of this communication is to present evidence in this connexion.

This evidence is obtained from a simple study of the neutron numbers, N, and atomic numbers, Z, of stable nuclei. If clusters are in fact entities inside the nucleus, one would expect the $(N - Z)$ systematics of stable nuclei to show a tendency for stable nuclei to be separated from each other by the subnuclear clusters. That such tendencies do in fact exist can be seen from the published work of one of us[2,3], and we present here further evidence by way of illustration. Fig. 1 is an $(N - Z)$ versus Z diagram on which the stable even-Z odd-N nuclides have been plotted. The following features emerge very clearly: (*a*) In the low-Z region the stable nuclides are separated from each other by steps of $^4_2$He. (*b*) For higher-Z (44–56) the separation is in steps of $^6_2$He and not $^4_2$He. (*c*) The sequences are interrupted by the 'magic numbers'.

It should be mentioned that the region Z 16–44 has been omitted in order to preserve clarity in presentation. In most of this region separations of both $^4_2$He and $^6_2$He appear—it may therefore be regarded as some sort of intermediate region.

If now the $^4_2$He steps in the low-Z region are taken as evidence of the presence of $^4_2$He clusters in low-mass nuclei (as indeed seems reasonable), then it appears likely that $^6_2$He clusters are present in certain nuclei of higher mass. The same effect obtains, although not so strikingly and with less clarity, if one plots stable odd–even or even–odd nuclides (see, for example, ref. 3, Fig. 3, and ref. 2, Fig. 19).

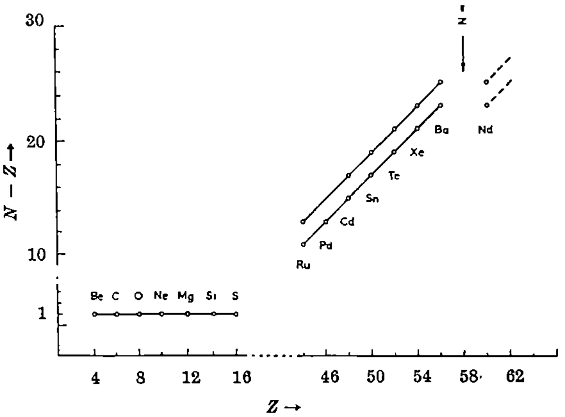

Fig. 1. $(N–Z)$ vs. Z diagram of stable even-Z, odd-N nuclides. The 'missing' nuclide $^{107}_{46}$Pd is very long lived with a half-life of 7×10^6 years

The evidence can be summarized as follows: (*a*) α-particle clusters appear to exist in the low-Z nuclei ($Z \leqslant 16$); (*b*) most of the region Z 16 to Z 44 appears to be a transitional region where the cluster can be either ${}^4_2$He or ${}^6_2$He; (*c*) from Z 44 to 56, ${}^6_2$He clusters appear to exist; (*d*) it seems likely that 'magic numbers' of protons or neutrons act as large clusters.

On this basis, then, one can (for some purposes, in any event) consider nuclei as consisting largely of 'closed shell' clusters plus one or more (seven appears to be a maximum number) smaller clusters of either ${}^4_2$He or ${}^6_2$He. If this is correct, it is, of course, most interesting to note that a cluster need not necessarily be an entity which is stable in itself (${}^6_2$He is unstable with a half-life of 0·8 sec.). A rough parallel to this situation exists in the neutron; although the neutron is itself an unstable particle, it can apparently be considered to exist as an entity in nuclei.

The question of neutron excess should also be mentioned. ${}^4_2$He has, of course, zero neutron excess, whereas ${}^6_2$He has $(N - Z)$ equal to 2. The transition from ${}^4_2$He to ${}^6_2$He clusters is therefore probably necessary in order to provide an adequate neutron excess to balance the Coulomb repulsion at higher Z. It should be noted that the discontinuities at the shell numbers always result in a reduction in neutron excess; ${}^6_2$He clusters evidently provide rather too much neutron excess.

In the region $Z > 60$, ${}^6_2$He-type regularities are also present, and several additional points of interest arise. These will be included in a more complete discussion (at present in preparation) of the cluster regularities observable in stable-nuclide systematics. At the same time, an effort is being made to investigate whether other nuclear properties exhibit ${}^6_2$He cluster effects in the appropriate regions of atomic weight.

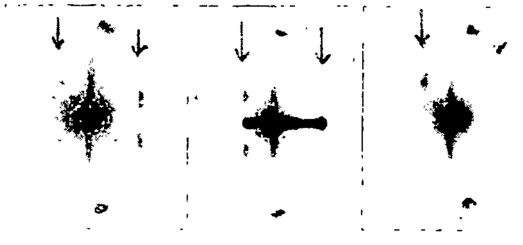
Extra Streaks in the X-ray Diffraction Pattern of Vanadium Single Crystals

Well-exposed Laue and oscillation photographs of vanadium single crystals show several streaks which can be easily distinguished from the Laue and Bragg spots and also from the diffuse areas of thermal scattering. Most of the following observations were made on specimens having at least one fairly bright (100) cleavage face of area 12–30 mm.^{2}. The specimens were electropolished.

The lattice parameter was derived by two independent measurements. (1) Powder photographs taken with a crushed single crystal using copper $K\alpha$ radiation and a 19-cm. Unicam powder camera. This method gave $a = 3{\cdot}036 \pm 0{\cdot}002$ A. (2) The separation of 110 Kossel lines on the single crystal photographs. This method gave $a = 3{\cdot}035 \pm 0{\cdot}001$ A. Both values agree well with the precision measurements of Neuburger[1] on high-purity oxygen-free vanadium powder, who found $a = 3{\cdot}0338 \pm 0{\cdot}0003$ A. at 25° C.

The Laue and oscillation photographs were taken with copper $K\alpha$ radiation using a Unicam single-crystal goniometer fitted with a quarter-cylinder camera (radius 114·6 mm.) and a modified version of the half-cylinder camera (radius 57·3 mm.). The latter was capable of covering the angular range from $\theta = 0°$ to 77° along the equator. Collimators of diameter ½ and ¼ mm. respectively were used. Ilford *G* X-ray film in a light-tight cellulose triacetate envelope was used. The envelope was covered with a nickel foil 0·020 mm. thick which served as a β-filter and also as an absorber of the fluorescent radiation generated in the specimen.

Powder photographs show nothing but fine continuous lines which may all be interpreted in terms of the body-centred cubic vanadium structure. The extra streaks (shown by arrows in Figs. 1,*a* and *b*) look similar to powder lines with strong preferred orientation. As the angle of incidence of the X-rays varies, the diffraction angles of the streaks remain constant, but their position along the 'powder lines' and their intensity change continuously. The intensity reaches its maximum near the centre of the angular range of incidence in which the streak is observable. This range of observability is 5°–6° for most streaks. For this reason the extra streaks on a Laue photograph and on an oscillation photograph taken around that particular stationary setting are similar (see Figs. 1,*a* and *b*). The streaks can thus be represented in reciprocal space by segments of concentric spherical shells around the origin of the reciprocal lattice. These segments subtend an angle of 5°–6° at the centre of the reflecting sphere and have maxima of intensity at their centres. Stationary-crystal photographs were taken in which the glancing angle of incidence of the X-rays on the (100) face was varied from 1° to 50°. In this angular range ten spherical shells were found and the radius of any given shell was the same for all specimens. The number of observed segments varied from one shell to another but on any particular shell it was the same for most of the specimens. One specimen, however, was found which showed a higher number of segments on some of its shells than did the other specimens. This particular crystal also behaved differently in another respect. For most specimens the arrangement of the segments on the shells conformed to the cubic symmetry of the whole crystal but the exceptional specimen showed a lower symmetry. This is illustrated by Fig. 1,*c*, which shows the extra streaks due to this specimen under the same conditions as for the usual specimens which gave Fig. 1,*a*. Fig. 1,*c* shows



(*a*) (*b*) (*c*)

Fig. 1. (*a*) Laue photograph taken at the 200 Bragg reflexion position with pairs of extra streaks on both sides of the Laue spot. (*b*) 5° oscillation photograph taken around the setting of Fig. 1,*a*. The extra streaks show no lateral shift. (*c*) Same as 1,*a*, but taken with the crystal which showed a greater number of extra streaks (see right-hand group). This photograph shows a horizontal plane of symmetry passing through the Laue spot for the positions, but not the intensities, of the extra streaks the extra streaks in the same positions but the intensities are different from those of Fig. 1,*a*.

A detailed study of the structural implications of the above findings and their possible interpretation is in progress, and the results will be published elsewhere.

Crystal Structure and Photoconductivity of Cæsium Plumbohalides

Wells[1] and his collaborators have shown that crystals of the general compositions $CsPbX_3$ with X = Cl, Br or I, and Cs_4PbX_6 with X = Cl or Br, may be prepared from aqueous solutions. I have investigated the structures of these crystals and also prepared a few more. I have found[2] that $CsPbCl_3$ and $CsPbBr_3$ have the perovskite structure. At room temperature they are tetragonally or monoclinically distorted. Both of them, however, show transition to pure cubic perovskite structure, at 47° C. and 130° C. respectively and with cell dimensions $a = 5\cdot605$ A. for $CsPbCl_3$, $a = 5\cdot874$ A. for $CsPbBr_3$. Whereas no extra or forbidden X-ray reflexions can be observed above these transition temperatures, $CsPbBr_3$ below 130° C.—and presumably also $CsPbCl_3$ below 47° C.—exhibit a new structure corresponding to a doubling of the cell dimensions. The transitions are likely to be of second order as $\Delta V = 0$ within the limits of accuracy of my measurements.

The $CsPbI_3$ crystals from aqueous solution are orthorhombic with space group No. 62 *Pnma* and $a = 4\cdot795$ A., $b = 10\cdot45_7$ A., $c = 17\cdot76$ A. The X-ray analysis yields all the atomic positions and interatomic distances: the lead atom is surrounded octahedrally by six iodine atoms at distances 3·01–3·42 A., and nine iodine atoms form distorted ditrigonal pyramids around each cæsium atom at distances of 3·87–4·19 A. The lead and iodine ions form chains of polynuclear complex ions parallel to the *a*-axis of the crystal. On heating these crystals to 305–308° C. they undergo a phase change and the colour changes from yellow to black. This black form which may also be obtained by melting cæsium iodide and plumbous iodide together in the correct stoichiometric proportion is rather unstable, and hence had to be investigated on a Geiger–Müller diffractometer. From its powder diagram it appears to have a monoclinically distorted perovskite structure ($a = b = 6\cdot15$ A., $c = 6\cdot23$ A., $\beta = 88\cdot15°$). It shows the same kind of superstructure as $CsPbBr_3$.

It is interesting to note that the above-mentioned crystals with perovskite structure are intensely coloured: $CsPbCl_3$ is pale yellow, $CsPbBr_3$ is orange and $CsPbI_3$ black, whereas crystals of the type Cs_4PbX_6 with X = Cl, Br or I are colourless. From this peculiarity one might guess that the former crystals also have special electrical properties. With a very crude apparatus we have found that the coloured $CsPbX_3$-crystals with perovskite structure are photoconductive, $CsPbCl_3$ having its maximum spectral sensitivity in the violet, $CsPbBr_3$ in the blue to green region and $CsPbI_3$ in the red region, that is, the spectral region which is complementary to the colour of the crystals.

A detailed account of this work will be published elsewhere.

Nuclear Magnetic Resonance in β-Brass

Bloembergen and Rowland[1] have shown that the addition of small amounts of zinc to copper reduces the intensity of resonance in the resulting alloy so that the line becomes unobservable when the zinc content reaches approximately 25 per cent. They explained this effect in terms of quadrupole broadening and pointed out that, in ordered structures with cubic symmetry, quadrupole broadening should be absent and a line would be expected. However, they found no resonance in a β-brass of about 50/50 composition (quoted by Bridgman[2] as 47·3 per cent zinc) and they suggested that the ordering was not complete.

Experiments in this laboratory have shown that there is a strong copper-63 resonance in a β-brass containing 48·33 per cent zinc by weight. The specimens were prepared by filing at room temperature and sieving through a 120-mesh sieve, annealing for 2 hr. at 450° C. in an argon atmosphere, and then slowly cooling to room temperature. The detecting apparatus was a conventional Pound–Knight–Watkins type of spectrometer operating at approximately 5·96 Mc./s. and a 'Varian' 12-in. electromagnet set at approximately 5,250 oersted. All experiments were done at room temperature.

The main features of the resonance line for the annealed powder are as follows: (1) The line is symmetrical with the centre located 5·2 kc./s. below that for well-annealed copper of 99·98 per cent purity under the same conditions. This means that the Knight shift ($\Delta H/H$) for copper in a well-ordered β-brass structure is approximately 0·14 per cent, as compared with 0·23 per cent for pure copper. (2) The integrated area under the absorption line is one-sixth of the area under a line obtained from a specimen of pure copper containing the same number of copper nuclei. (3) The line for β-brass is appreciably narrower than that for pure copper, this smaller dipole broadening being consistent with the fact that the next nearest copper neighbours are farther away than they are in pure copper. (4) The line can be eliminated almost completely by plastic deformation. This was shown by testing a specimen immediately after filing and sieving.

The detailed effects of deformation, heat treatment, and variation of composition have been studied and will be described elsewhere.

A Method for Determination of Particle Penetration Depths in a Filter

A DETAILED knowledge of how particles penetrate a filter when an aerosol is filtered can give a good deal of information about properties of both filter and particles. In this communication, a simple method for the determination of particle penetration is described.

An aerosol, consisting of radioactive solid particles 0–2μ in diameter, was filtered at an air velocity of 100 cm./sec. through a glass-fibre paper (L.O.F. Glass Fibre Co., 475 Code 106 *AAA* glass, 0·2 mm. thick, 58 gm./m.², 'volume-surface' fibre diameter[1] 0·6μ).

225 cm.² of this filter was pressed against a gummed cellulose-acetate film, with the air-entry side of the filter downmost. On removal, a thin layer of glass fibre was left on the sticky surface. The process was repeated until the whole filter was divided into twenty such layers each about 10μ thick. It was difficult to obtain layers of equal thickness, especially at the end of the process, when the sticky films now and then tore thicker pieces from the remaining glass-paper. The weights of the layers (after ashing of the sticky film) were found to vary between 30 and 80 mgm., the average being 60 mgm.

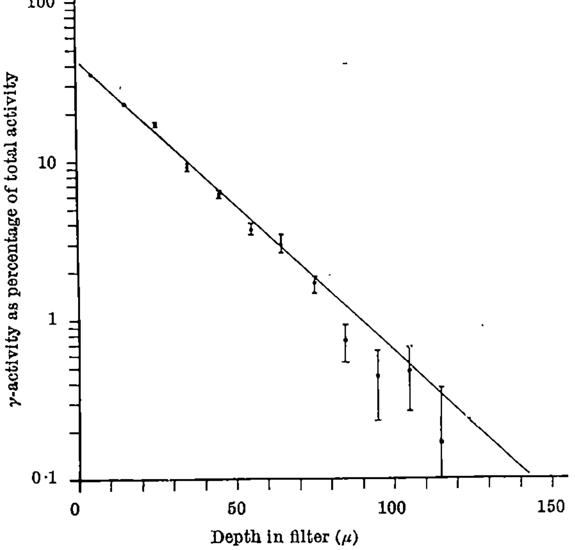

Fig. 1. γ-activity of filter layers as a function of depth in filter

Each layer was radioautographed and the γ-activity measured with a scintillation counter. The autoradiograph spots were counted and divided into five size classes, which were attributed to corresponding classes of radioactive strength by calibrating with active particles of known strength. The activity of the different particles being known, their sizes could thus be approximately determined.

The results are given in Figs. 1 and 2. An interesting phenomenon, which, so far as I know, has not

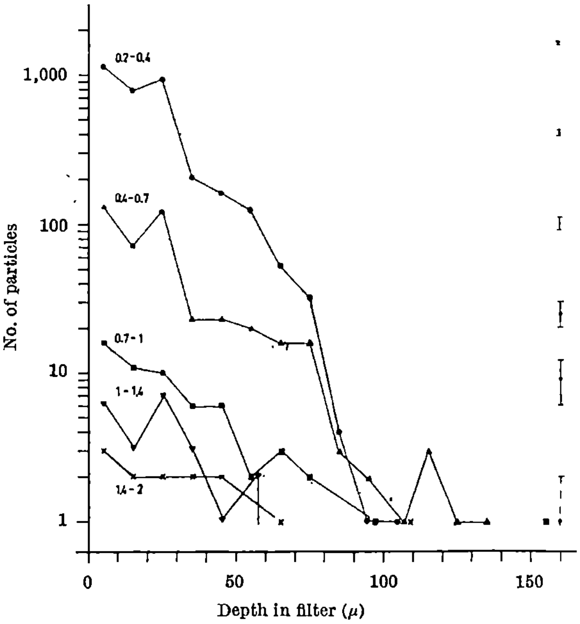

Fig. 2. Number of particles in filter layers as a function of depth in filter. The figures on the left are the range of particle diameters in μ. Statistical errors are given on the right

been dealt with before, is that the bigger particles are more likely to penetrate deep into the filter than the smaller ones, indicating that they are shot into the filter by the fast air stream, pushing the fibres out of the way and penetrating deeper the more momentum they have, instead of being stopped by the first filter fibre they meet.

On account of the wide variations in the weights of the layers mentioned above, it might have been expected that the plot of activity against depth (Fig. 1) would be more irregular. However, the excess weights of the heavier layers are mainly due to material from parts of the filter with lower activity. The error in the activity of a layer will therefore seldom be positive and, in fact, it is likely to be more negative the deeper the layer. This tendency of the error may be expected to give the graph a steeper slope than it ought to have. The method may possibly be improved in this respect, perhaps by using laminated filters.

Comparison of Measured and Computed Values of the Rapid Fading-Rate of Ultra High-Frequency Signals reflected from the Moon

DURING August 1957, a bistatic moon reflexion experiment was carried out between South Dartmouth, Massachusetts (41·5395° N., 70·9512° W.), and Alpha, Maryland (39·3224° N., 76·9258° W.). The continuous-wave transmitter fed approximately 40 kW. of power, at a frequency of 412·85 Mc./s., into a horizontally polarized feed mounted in a 60-ft. diameter parabolic antenna. The antenna was movable in azimuth and elevation. The receiving system at Alpha used a dual-polarization feed in a 28-ft. diameter parabolic antenna, which was free to move in azimuth and elevation.

Two identical receiving systems were used, with band-widths of 50 c./s. With front end noise figures of approximately 5 db., maximum signal to noise ratios of approximately 25 db. were obtained. A common local oscillator was varied in frequency so that the changing Doppler frequency of the moon-reflected signal could be followed.

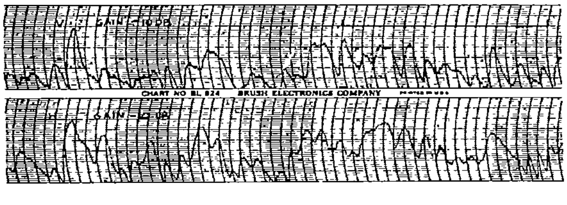

Fig. 1. Moon signal: examples of fading-rates. 1538 E.S.T. Top, vertical; bottom, horizontal. Scale, 10 sec.

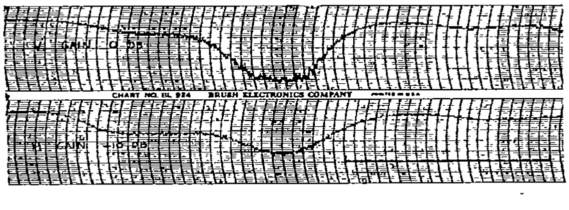

Fig. 2. Moon signal: examples of fading-rates. 0854 E.S.T. Top, vertical; bottom, horizontal. Scale 10 sec.

The system was operated from moonrise to moonset each day during August 6–August 29, 1957, apart from interruptions caused by equipment difficulties. The usual effects due to Faraday rotation were noted; that is, the individual signal-levels varied with periods of hours while the total received signal power-level remained quite constant, apart from the slow change due to the varying Earth–Moon distance.

The rapid fading-rate of the signals detected was observed to vary during the course of the experiment, from a maximum of several cycles per second to minimum rates at which the signal-levels remained almost constant for several minutes. Fig. 1 shows a typical fading-rate (with a detector time constant of 0·015 sec.), while Fig. 2 shows a very low fading-rate period.

It seemed reasonable to assume that the total effective libration rate of the Moon had a strong influence in producing these varying fading-rates[1]. For example, if the Moon is assumed to possess just three small reflecting regions, a central one and two others symmetrically located with respect to the centre, then a continuous wave signal would be reflected with small Doppler side-bands, in addition to the over-all Doppler shift. After detection, the side-bands would show up as effective 'fading' of the signal. Now in practice many portions of the Moon are effective in giving rise to appreciable reflexions, although a precise description of the mechanism is not possible. However, if on the Moon's surface one considers a circle drawn the radius of which is a given fraction of the full radius of the Moon, then one can examine all points on this circle and determine the maximum magnitude of the Doppler spread. By comparing this number with the observed fading-rate (defined in some rather arbitrary but consistent manner) it is then possible to determine whether or not the variations in fading-rate of the received signals are due primarily to a Doppler spread caused by libration.

A programme has been written for the *IBM* 704 computer which yields the over-all Doppler shift and libration-rate. Further trigonometry then enables these data to be converted into Doppler spread. Two subdivisions were made in the programme. (1) First-order differences only were retained, leading to a result which was normalized with respect to the Moon's radius. (2) Further refinements were introduced, leading to computations which could not be normalized, but which had to be carried out for a number of values of fractional radii of the Moon.

Results obtained from (1) are shown in Figs. 3 and 4, with a figure of 0·67 used for the fractional radius of the Moon. That is, the computed 'fading-rates' are actually computed maximum Doppler spreads on a circle of two-thirds the Moon's radius. The observed fading-rates were obtained by counting maxima of the detected signal over an interval of a minute or so at each period.

In general, results from (2) above were not significantly different from results obtained from (1). At periods of very low fading-rate the computed values from both (1) and (2) showed spreads of the order of 0·01 cycle per second, while the observed fading-rates often were considerably less than this.

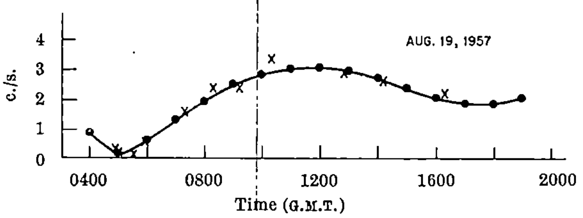

Fig. 3. Fading-rate of signal reflected from the Moon. ●, Computed ; ×, experimental

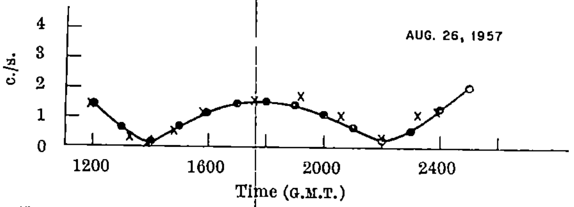

Fig. 4. Fading-rate of signal reflected from the Moon. ●, Computed ; ×, experimental

It appears that the limiting factor in the accuracy of the computation is probably the somewhat abbreviated values of selenographic latitude and longitude, published in the American Ephemeris and Nautical Almanac. However, apart from the periods of very low fading-rate, excellent agreement was obtained between measured and computed values. Hence, for frequencies in the ultra high-frequency band, it appears that the rapid fading of a signal reflected from the Moon can be predicted in some detail from dynamical considerations. Thus other effects, for example, those which might be due to the ionosphere, must be correspondingly limited. Any extreme effect, such as that which might occur during auroral activity, might show up experimentally as a noticeable departure from the computed values.

It is a pleasure to acknowledge the assistance of the staff of the Massachusetts Institute of Technology Round Hill Field Station at South Dartmouth, Massachusetts, and many others in the Lincoln Laboratory who took part in the experiment.

This work was supported jointly by the U.S. Army, Navy and Air Force under contract with the Massachusetts Institute of Technology.

Possible Causes of Geomagnetic Fluctuations having a Six-Second Period

Geomagnetic fluctuations of two different types in the frequency-range 0·1–30 c./s. have recently been reported by Duffus *et al.*[1]. Fig. 2 of their communication shows that one of these types closely resembles two other naturally occurring oscillations, and has a period (about 6 sec.) of the same order as the latter. These two naturally occurring (and probably associated) oscillations are microseisms and microbaroms, and one or the other of them may be the cause of the observed magnetic oscillations.

If the pick-up loop used for recording the variations of the magnetic field was so mounted that the microseismic oscillations of the Earth's crust could have caused rotation of the loop with respect to the Earth's permanent magnetic field, it is possible that currents having the same frequency as the microseisms could have been induced in the loop. Because of the very large wave-lengths of the seismic oscillations, however, this explanation seems somewhat improbable. (The entire loop would tend to move up and down as a unit rather than rotate.)

It seems somewhat more probable that the observed magnetic effects result from atmospheric oscillations of the same period. These oscillations were first observed by Benioff and Gutenberg[2,3], and were named by them microbaroms. Microbaroms have also been studied by other workers[4–7]. It has been pointed out by Daniels[6] that the particle amplitude of microbaroms would be much greater at ionospheric levels than at the Earth's surface, the amplification being of the order of 1,800 at an altitude of 120 km. Particle velocities of the order of 40 cm. sec.$^{-1}$ would therefore occur at this altitude if the pressure amplitude at the Earth's surface were 1 dyne cm.$^{-2}$ (a value which is occasionally observed).

A detailed theory explaining how an atmospheric oscillation having such a period and velocity can give rise to a magnetic fluctuation still remains to be formulated. The relationship between the magnetic and microbarometric oscillations could, however, be studied experimentally by making simultaneous observations of the two phenomena. A similar study was made by Saxer[7] for the purpose of establishing a correlation between microbaroms, microseisms and ocean waves. One difficulty connected with such a study is that the microbarometric pressure variations are so small that they are often masked by pressure fluctuations due to atmospheric turbulence. This interference, however, could be minimized by using an infra-sonic line microphone of the type invented by Daniels[8] with which an improvement in the signal-to-wind-noise ratio of as much as 20 db. can be achieved at frequencies in the region of interest.

Zeta Potential and Sedimentation Behaviour in Flocculated Cane Sugar Juice

The stability of an aqueous suspension is reflected in both sedimentation-rate and sedimentation-volume[1,2]. In a stable system, settling of the single particles is slow, but they remain free to move independently of each other into positions of close packing in the sediment. In the unstable and flocculated system, settling of the particle aggregates is rapid, but their packing in the sediment is now of a random nature and the sedimentation volume is large. When the flocculation of a stable suspension is brought about by a decrease in zeta potential, both settling-rate and sedimentation-volume increase as ζ approaches zero.

When flocculation of the suspension is not brought about by a change in ζ, the particles within a floc still carry their original electrostatic charge. The question then arises: To what extent can a change in ζ now affect the sedimentation behaviour of the flocs ?

Cane juice is a protein-stabilized suspension of waxy and other particles[3] which may be flocculated by the precipitation *in situ* of calcium phosphate; in this case complete destabilization occurs with no appreciable change in ζ. The flocs are composed of clusters of particles bound together in a matrix of the inorganic precipitate[4] and they settle to give a mud volume approximately twenty-five times the total volume of particles and precipitated material. It is therefore of interest to study the effect of a decrease in ζ upon the sedimentation of this unstable system in which flocculation is effectively independent of ζ.

Fig. 1 shows the effects on sedimentation and zeta potential of two detergents, cetyltrimethylammonium bromide and sodium laurylsulphate. The experimental method used to assess sedimentation behaviour has been fully described in another paper[5], where the calculation and significance of the settling constant K (the velocity of the interface when the volume of mud is twice that after infinite settling time) and the sedimentation volume H_∞ (the volume percentage of mud after infinite settling time) are fully discussed. Determination of electrophoretic mobilities was carried out by a microelectrophoresis technique fully described in another paper[6]. Mobilities could not be measured directly on settling-tube contents, but were measured on samples of juice diluted twenty-fold with 0·01 M potassium chloride in the required concentration of detergent. Since the sedimentation behaviour curves are symmetrical about the reversal of charge concentration of cetyltrimethylammonium bromide (0·37 mM) determined on these diluted samples it must be concluded that the same reversal of charge concentration would have been found in the settling-tube contents. Consistent with this observation, it may be noted that in oil/water emulsions stabilized by bovine serum albumin the reversal of charge concentration of myristyltrimethylammonium bromide is 0·36 mM and this value is independent of concentration of both total protein and oil drops (Bennett, M. C., and Haydon, D. A., unpublished work).

The outstanding feature of the sedimentation behaviour lies in the fact that there is a maximum in settling-rate at the reversal of charge point and that this is accompanied by a minimum in sedimentation-volume. The occurrence of a minimum in sedimentation-volume shows that the decrease in ζ has not led to an increase in particle aggregation, and it follows that the maximum in settling-rate must be attributed to a more closely packed arrangement of particles within the floc itself. On the basis of the floc structure described above it may therefore be suggested that mutual electrostatic repulsion between individual particles in a floc tends to maintain a less closely packed spatial arrangement than might be assumed by uncharged particles. A decrease in particle charge should therefore lead to a more compact floc structure, which must be accompanied by an increase in settling-rate and a decrease in sedimentation-volume.

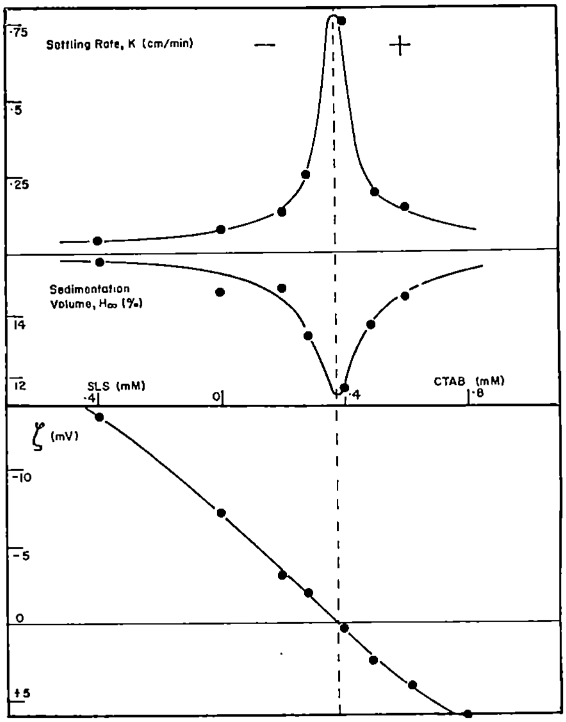

Fig. 1. Settling rate, sedimentation volume and zeta potential against concentration of cetyltrimethylammonium bromide (CTAB) and sodium laurylsulphate (SLS)

In similar studies on other cane juices it has been possible to demonstrate marked deviations from the behaviour described here. In one case, the H_∞ curve showed a slight maximum at the reversal of charge point; it was shown that this juice was abnormally stable towards calcium phosphate precipitation so that a reduction in zeta potential was accompanied by an appreciable decrease in stability and an improvement in flocculation. In some juices, the flocculated system was found to be completely insensitive to the action of detergents, while in others the reversal of charge concentration of cetyltrimethylammonium bromide was found to have increased to as much as 0·70 mM. In every case it is believed that these deviations are associated with the presence at the particle surface of layers of various polysaccharide materials; the evidence is discussed elsewhere[6].

Effect of γ-Aminobutyryl-Choline upon the Electrical Activity of the Cerebral Cortex

RECENTLY, Kuriaki[1] succeeded in synthesizing γ-aminobutyryl-choline and obtained some evidence of its presence in the brain. In the present study we have observed its effects on the electrical activity of the cerebral cortex.

Experiments were carried out on ten rabbits and a few cats under urethane anæsthesia. Evoked potentials were led off by means of a unipolar silver wire electrode with a ball tip (diam. 0·5 mm.) placed on the pial surface.

For electrical stimulation, square-wave pulses of 0·02–0·1 msec. were used. Shock artefacts were minimized by the use of an isolation transformer. Potentials were recorded by a condenser-coupled amplifier (time constant 0·5 sec.) led to a dual-beam oscilloscope.

All the test solutions were applied locally to the cortical surface with squares of filter paper approximately 2·0 mm. × 2·0 mm.

The primary sensory potential complex evoked and recorded from the surface of the sensory cortex in response to the stimulation of the contra-lateral peroneal nerve consists of an initial surface-positive potential followed by a surface-negative wave.

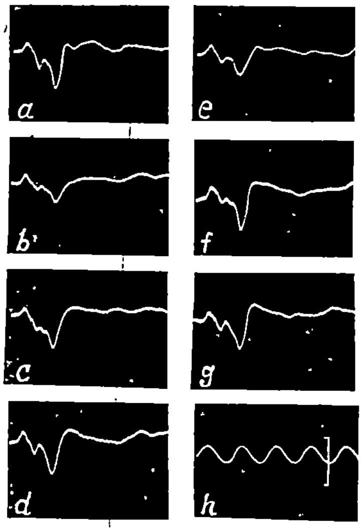

Fig. 1. Effect of γ-aminobutyryl-choline on the primary sensory potential evoked by stimulation of the contra-lateral peroneal nerve. Left-hand column: *a*, control; *b*, 30 sec. after the application of $4 \cdot 0 \times 10^{-4}$ *M* γ-aminobutyryl-choline; *c*, *d*, respectively, 30 sec. and 5 min. after the cortex was washed with Ringer solution. Right-hand column: *e*, 3 min. after $4 \cdot 0 \times 10^{-5}$ *M* γ-aminobutyryl-choline; *f*, *g*, recovery of responses 1 and 2 min. after washing off γ-aminobutyryl-choline; *h*, 50 c.p.s. The vertical bar represents 0·5 mV.

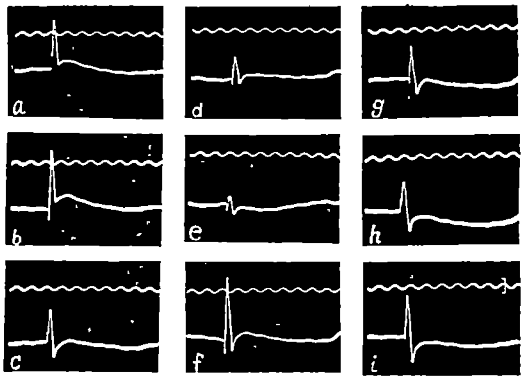

Fig. 2. Effect of γ-aminobutyryl-choline on the dendritic potential at 2 mm. distant from the stimulating electrodes in a rabbit. Records *a*, *b*, control; records *c*, *d*, *e*, 3, 4 and 6 min. after $4 \cdot 0 \times 10^{-3}$ *M* γ-aminobutyryl-choline; record *f*, 2 min. after washing off γ-aminobutyryl-choline. Response increased for some minutes. Record *g*, 16 min. after washing; record *h*, 5 min. after $4 \cdot 0 \times 10^{-4}$ *M* γ-aminobutyryl-choline; record *i*, recovery 1 min. after washing

Topical application of γ-aminobutyryl-choline to the sensory cortex resulted in rapid decreases in the surface-positive as well as surface-negative phase of the evoked potential.

The concentrations which caused appreciable depression were $4 \cdot 0 \times 10^{-5}$–$4 \cdot 0 \times 10^{-4}$ mol./l. An example is shown in Fig. 1. In addition, there was a prolongation of the surface-positive wave.

Depression of the primary sensory evoked potential occurred at once after the application. Washing the substance from the cortex resulted in rapid recovery (almost within 30 sec.) of the original wave form.

γ-Aminobutyryl-choline exhibited marked inhibitory action on the local electrical response of the cortex to direct surface stimulation. The response was led off at 2 mm. distant from the stimulating electrodes. γ-Aminobutyryl-choline was applied to the locus where the response was recorded.

With stronger stimulation, the direct cortical response consists of an initial surface-negative wave followed by a positive wave and a secondary surface-negative slow wave. γ-Aminobutyryl-choline depressed rapidly two surface-negative components, but left the surface-positive component almost unaffected for a few minutes. Using concentrations greater than $4 \cdot 0 \times 10^{-5}$ mol./l., we observed the striking inhibitory action of γ-aminobutyryl-choline on the direct cortical response.

On washing the chemical from the cortex, immediate recovery took place; though an increase in amplitude of the initial negative component beyond the original was sometimes observed in the beginning phase of the recovery. A typical example is given in Fig. 2.

The inhibitory action of γ-aminobutyryl-choline on the metrazol-convulsive spikes was compared in the same rabbits with that of γ-aminobutyric acid, the inhibitory action of which on the electrical activity of the cortex has been reported by some investigators[2,3].

γ-Aminobutyric acid could induce complete inhibition of the excitation by 10 per cent metrazol in the concentration of $1 \cdot 0$–$5 \cdot 0 \times 10^{-1}$ mol./l. On the other hand, γ-aminobutyryl-choline, at $2 \cdot 0$–$4 \cdot 0 \times 10^{-4}$ mol./l., caused complete inhibition. That is, the inhibitory strength of γ-aminobutyryl-choline was about 500–1,000 times as powerful as that of γ-aminobutyric acid.

We consider that γ-aminobutyryl-choline may be the true physiological inhibitory substance in brain. A fuller account will be reported elsewhere.

We are thankful to Prof. Kuriaki and Daiichi Seiyaku Co. for the gift of γ-aminobutyryl-choline.

Production of Glucose by the Liver during Hyperglycæmia

The effect of hyperglycæmia on hepatic glucose output has been studied employing an isotope dilution technique. Glucose labelled with carbon-14, of the same specific activity as the blood glucose, was injected in amounts sufficient to produce hyperglycæmia. The selection of the appropriate specific activity for this glucose 'load' was made easier by a procedure in which an infusion of labelled glucose (in 'weightless' amount) was continued throughout the experiment. During such an experiment the blood glucose specific activity remains relatively constant so long as the flow of unlabelled glucose from the liver continues at a uniform rate. On the other hand, the specific activity of the blood glucose rises if the flow of unlabelled glucose from the liver stops or decreases[1]. The present technique avoids the misleading values for plasma glucose specific activity which might result from slow mixing of injected unlabelled glucose with a labelled body glucose pool[1].

In two experiments in pentobarbital anæsthetized dogs, an amount of glucose with an appropriate specific activity was injected to produce hyperglycæmia (Fig. 1). During the period of hyperglycæmia the blood glucose specific activity did not rise. This indicates that the output of unlabelled glucose by the liver continued during the period of hyperglycæmia.

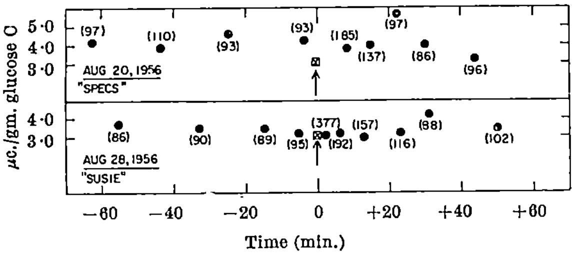

Fig. 1. Carbon-14 concentration in blood glucose before and after the injection of a glucose load and during a constant infusion of glucose-^{14}C in 'weightless' amount. The carbon-14 concentration of the glucose load, 1 ml. of 30 per cent (w/v) glucose/kgm. dog weight, is shown by the location of the × enclosed in a square at zero time (the mid-point of the load injection interval of 2–3 min. duration). Blood glucose concentrations in mgm. glucose per 100 ml. whole blood are given in parenthesis above or below each point showing carbon-14 concentration. Randomly labelled glucose-^{14}C was used in these experiments

These studies, therefore, do not support the conclusion[2,3], based on measurements of liver blood flow and differences of hepatic arteriovenous blood glucose concentration, that hyperglycæmia stops net hepatic glucose output. However, there is not necessarily a conflict between the present studies and these previous findings, since among the determinants of net hepatic glucose output are factors which are not measured by the isotope technique.

The uptake and output of glucose by the liver after a large amount of glucose is administered may involve several metabolic processes. Storage (whether in extracellular fluid, intracellular fluid or as preferentially removable end-groups of glycogen[4]) of blood glucose may occur during hyperglycæmia, followed by loss to the blood of the same glucose molecules as the blood glucose concentration returns to normal. In addition, during hyperglycæmia there may be increased utilization by the liver of circulating glucose for carbon dioxide production or for net synthesis of non-carbohydrate materials. These processes will influence the net difference between glucose entering and leaving the liver as determined by hepatic venous catheterization methods, but, there being no dilution by glucose-^{12}C, they will not be reflected in hepatic glucose production as measured by isotope dilution techniques.

The net production of new glucose molecules in the hepatic cell influences the measurement of net glucose output in catheterization studies and is thought to be almost entirely responsible for the decrease in specific activity observed in experiments employing isotopic tracer methods to determine hepatic glucose output. This process is of particular interest with regard to diabetes mellitus, because it has been implied[5] that insulin acts directly to stop hepatic glucose output during hyperglycæmia in the normal animal, whereas in the diabetic animal the absence of insulin eliminates this direct control mechanism.

It is conceivable also that an exchange of carbon-14 and carbon-12 atoms via the metabolic intermediates in the liver cell might contribute to a decrease in specific activity during isotope dilution measurements in certain circumstances. For example, an increased turnover of liver proteins during hyperglycæmia might introduce more carbon-12 atoms into the metabolic intermediates common to carbohydrate and amino-acid metabolism and simultaneously remove more carbon-14 atoms in the direction of protein synthesis. The end result would be a more rapid dilution of the circulating labelled glucose, whereas no increase in net protein degradation or net glucose production had occurred.

From the above it is concluded that the undiminished rate of dilution of labelled blood glucose during hyperglycæmia in the anæsthetized normal dog reported here must be interpreted as indicating either: (1) that the production of glucose in the hepatic cell continues during hyperglycæmia, or (2) if glucose production does cease there is a concomitant increase in an exchange process of the kind discussed above.

In previous applications of the isotope dilution technique to this question the results have been interpreted as indicating that hepatic glucose production ceases during hyperglycæmia[5,6]. In these earlier studies a glucose-^{12}C 'load' was administered after a single injection of glucose-^{14}C and consideration was not given to the slowness with which intravenously injected glucose mixes with a part (about half) of the glucose pool.

'Karathane' : the Relative Importance of the Phenolic and Unsaturated Acid Components in Toxicity towards Certain Plant Pathogens

THE commercial acaricide and fungicide currently offered as 'Karathane' has been shown to be one of the few substitutes for sulphur for the control of powdery mildews on a number of crops. The active ingredient is stated to be 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate, although some of the phenol is usually present in the free state.

Rich and Horsfall[1] reported that "laboratory and greenhouse tests showed that tenacity and phytotoxicity are due to the dinitrocaprylphenyl portion of the molecule, while the fungitoxicity is due to the crotonic acid portion". It was later learned (Rich, S., private communication) that this view was based on glass-slide experiments using spores of *Stemphylium sarcinaeforme* (Cav.) Wiltsh. as test organism, a spore suspension being added to the slide cavity after drying the initial solution or suspension of test substance. Germination was not inhibited by 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate, 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenol or crotonic acid alone, or by a mixture of the second and third, even at 0·1 per cent. If, however, the spores were added to a crotonic acid solution and this suspension incubated on slides, the *ED*50 was less than 0·003 per cent. These results were interpreted to mean that crotonic acid was easily lost from the ester and from a deposit on glass, and that fungitoxicity of 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate depended on crotonic acid being present at the time of interaction with spores.

In greenhouse investigations begun here in 1952 on the chemical control of apple powdery mildew, *Podosphaera leucotricha* (Ell. and Everh.) Salm., using M.III rootstocks in small pots, no promise of control was offered at 0·05 per cent by salts or simple esters of crotonic acid, or by a considerable range of esters of unsaturated acids or alcohols, or by various other compounds containing unsaturated bonds in the molecule. On the other hand, technical grade 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate or the free phenol, isolated from the crude ester, gave, at 0·025 per cent, prophylactic control of the disease equal to that given by 1 per cent lime-sulphur, indicating that the phenolic portion of the 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate molecule is mainly responsible for fungitoxic action, in this case at least.

Recently, a more satisfactory method of infection has made possible more critical tests. Ten pots, each with one barley seedling or one apple rootstock bearing 2–3 shoots, were used for each treatment. Chemicals in aqueous formulation (1 per cent acetone and 0·025 per cent 'Triton *X*-100') were applied by dipping ; spores were applied later by settling in a tower. Lesions were counted after 7 days for barley and 9 days for apple. It is hoped to publish full details of the methods elsewhere.

The results of two trials on barley and one on apple are given in Table 1, the 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate and the free phenol being used in equimolar ratios, and ammonium crotonate in equimolar, quadrimolar or quinquemolar ratio. In all three tests, the free phenol gave as good protection as the ester, whereas ammonium crotonate gave little or no protection against barley mildew, and only 60 per cent reduction of apple mildew at the quinquemolar rate.

Table 1

Treatment	Concentration (per cent)	Barley		Apple
		Lesions per plant : First trial	Second trial	Lesions per leaf
Formulation control	—	40·9	92·5	6·87
DNOP	0·020	0·3	—	0·0
	0·016	—	0·2	—
DNOPC	0·025	0·2	—	0·0
	0·020	—	0·8	—
Ammonium crotonate	0·007	41·5	—	—
	0·028	—	115·2	—
	0·035	33·6	—	2·74

DNOP = the free phenol; DNOPC = 2 : 4-dinitro-6-(1-methyl *n*-heptyl)phenyl crotonate.

Further greenhouse trials have shown that control of apple and barley mildews comparable to that given by 1 per cent lime-sulphur can be obtained under these conditions with the free phenol at 0·0025 and 0·007 per cent, respectively. Moreover, a large degree of control was achieved at 0·01 per cent with 2 : 4-dinitro-6-*n*-octylphenol on apple, and with 2 : 4-dinitro-6-*cyclo*octylphenol on barley ; all the octyl isomers caused scorching of barley leaves, and the *cyclo*-octyl compound was toxic to apple also. The 6-*n*-hexyl and 6-*n*-heptyl homologues were also effective on apple, but very toxic to barley : the 6-*cyclo*hexyl homologue, dinex, was almost non-toxic to barley even at 0·05 per cent, but mildew control was poor. The 6-chloro homologue was very promising on barley, but very toxic to apple, at 0·02 per cent ; picric and picramic acids were safe at 0·015 per cent on barley but afforded little control of mildew.

It is well known that powdery mildews are largely unaffected by chemicals that are toxic to many other types of fungi. Thus the results obtained with 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate and its components on two powdery mildews, which were diametrically opposite to those reported by Rich and Horsfall for *S. sarcinaeforme*, might be peculiar to the Erysiphaceae. Results are therefore of interest from tests conducted with two well-known fruit pathogens, *Venturia inaequalis* (Cke) Wint., and *Botrytis cinerea* Pers. ex Fr., using a glass-slide spore-germination technique already described[2] that is basically similar to that used by Rich and Horsfall.

Table 2

Treatment	Concentration (per cent)	Inhibition of germination (per cent)	
		V. inaequalis	*B. cinerea*
DNOP, freed from ester	0·01	100	10·3
	0·001	33·5	1·5
	0·0001	4·6	0·0
DNOPC, freed from phenol	0·01	100	1·2
	0·001	19·2	0·0
	0·0001	14·6	0·0
DNOPC, crude	0·01	100	2·8
	0·001	31·1	0·0
	0·0001	0·0	0·0

DNOP = the free phenol; DNOPC = 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate.

Formulation was in 8 per cent acetone and 0·05 per cent sulphite lye, the spore suspension being placed on the dry deposit. The results obtained with both organisms, corrected to the formulation control by Abbott's formula, are given in Table 2, and leave little doubt that the activity of 2 : 4-dinitro-6-(1-methyl-*n*-heptyl)phenyl crotonate, crude or purified, is due almost entirely to the phenolic component, the ester probably being decomposed at some stage after deposition on glass, as it may well be on foliage.

We are indebted to our colleagues, Mr. R. P. Tew, for provision of 2 : 4-dinitro-6(1-methyl-*n*-heptyl)phenyl and several *n*-alkyl homologues, and Dr. M. H. Moore, for much help in developing methods and for recording the first series of trials, and to British Oxygen Research and Development, Ltd., for a gift of the *cyclo*-octyl homologue.

Biosynthesis of Plant Glycosides from Uridine Diphosphate Glucose

The formation of glycosides and gentiobiosides after adding phenols or other substances to whole plant tissues has been observed by several workers[1-3]. Extracts of *Vicia faba* were reported by Miwa *et al.*[4] to form glucosides from vanillin, salicylaldehyde and hydroquinone. Tabone[5] prepared a partially purified enzyme from lentils which on addition of uridine diphosphate glucose and anthranilic acid formed a compound in which the carboxyl group of anthranilic acid was joined to a β-glucosyl residue.

The formation of phenol glycosides has been reported previously[6]: incubation of wheat-germ extracts with uridine diphosphate glucose and hydroquinone was found to lead to the appearance of a compound which appeared to be identical with arbutin (*p*-diphenol-β-glucoside) as judged by its mobility on paper before and after acid or enzymatic hydrolysis. Incubation of hydroquinone with other possible glucose donors, such as glucose-1-phosphate, sucrose, cellobiose or maltose gave negative results. Other phenols, such as saligenin (*o*-hydroxybenzyl alcohol), pyrocatechol (*o*-diphenol) and resorcinol, also reacted in the system to yield the corresponding β-glucosides, that is, salicin, pyrocatechol- and resorcinol-β-glucoside respectively.

In the course of studies on the formation of hydroquinone glucoside, it was observed that another substance besides arbutin was formed. As shown in Table 1, an unknown compound was found (R_F 0·08) in addition to hydroquinone (R_F 0·83) and arbutin (R_F 0·35) when the reaction mixture was chromatographed on paper.

In view of the lower mobility, it was considered likely that the compound with R_F 0·08 might have more than one glucose residue. Experiments carried out with arbutin instead of hydroquinone as substrate showed that the slowly moving compound (R_F 0·08) was formed more rapidly and in larger amounts. Up to 0·2 μmole was formed in 30 min. in the system mentioned in Table 1, with 2 μmoles of arbutin in place of 10 μmoles of hydroquinone.

For the identification of the new compound the reaction products were run on paper with butanol/pyridine/water (6 : 4 : 3) as solvent, thus obtaining a good separation from free glucose and from another unknown substance which remains near the origin with aqueous butanol. The new substance, after rechromatography and elution from the paper, gave an absorption curve in the ultra-violet very similar to that of arbutin. After acid hydrolysis in 1 *N* hydrochloric acid for 60 min. at 100° C. followed by paper chromatography, only glucose and hydroquinone were detected. Incubation with purified emulsin for 24 hr. gave glucose, arbutin and hydroquinone.

Estimation of phenol by the method of Folin and Ciocalteu[7] against an arbutin standard and of glucose by the phenol/sulphuric acid procedure[8] showed that the ratio glucose/phenol was about 2. The same results were obtained by estimating the glucose with an alkaline copper reagent[9] after complete hydrolysis with emulsin. By partial acid hydrolysis (10 min. in 1 *N* hydrochloric acid at 100°) followed by paper chromatography and development with alkaline silver[10] it was found that in addition to glucose a more slowly migrating sugar appeared. The latter was separated from parallel runs and compared with different disaccharides. Its behaviour proved to be identical with that of gentiobiose upon paper chromatography with several solvents (butanol/pyridine/water, 6 : 4 : 3; butanol/acetic acid/water, 4 : 1 : 5; and propanol/ethyl acetate/water, 7 : 1 : 2), and only glucose was formed on acid hydrolysis. Thus the results indicate that the compound is β-gentiobiosylhydroquinone. No mono- or di-glycosides were detectable in experiments in which the following substances were substituted for uridine diphosphate glucose: uridine diphosphate-acetyl glucosamine, guanosinediphosphatemannose, sucrose, glucose-1-

Table 1

Addition	Hours of incubation at 37° C.	R_F		
Uridine diphosphate glucose (1 μmole)	3	0·08	0·35	0·83
—	3	—	—	0·83
Arbutin (2 μmoles)	0	—	0·35	0·83
Arbutin (2 μmoles)	3	—	0·35	0·83

The system contained: 10 μmoles of hydroquinone, 50 μmoles of *tris* buffer *p*H 7·4 and 0·1 ml. of enzyme. Total volume 0·3 ml. The enzyme was prepared by extracting wheat germ with 3 volumes of 0·05 *M* phosphate buffer of *p*H 7, precipitating with ammonium sulphate between 0·2–0·5 saturation and dialysing. The deproteinized samples (ref. 9) were spotted on paper and run for 20 hr. with *n*-butanol saturated with water. Diazotized *p*-nitroaniline was used as developer (ref. 11).

phosphate, cellobiose, gentiobiose or maltose. Arbutin by itself was not hydrolysed or transglycosidated by the wheat-germ extracts, so that the mechanism of action is different from that described by Pridham[11], who reported the formation of β-gentiobiosyl-hydroquinone and glucose from arbutin with a plant β-glycosidase.

It thus appears that two transfer reactions from uridine diphosphate glucose are catalysed by the wheat-germ extracts: (1) the formation of the β-glucoside of hydroquinone (arbutin) and (2) the glycosylation of the glucose residue of the latter at the 6 position to yield gentiobiosyl-hydroquinone. It has not been established whether one or two enzymes are involved.

This investigation was supported by research grant *G*3442 from the National Institutes of Health, United States Public Health Service.

Failure to induce Immunological Tolerance during Recovery from Irradiation

Neonatal animals and animals given large doses of whole-body X-irradiation are immunologically similar in two important respects: both are very poor producers of antibody, but both become satisfactory producers of antibody after several weeks, presuming that the X-irradiated animals survive. It is well established that during normal maturation animals go through a stage during which they may be rendered immunologically tolerant of certain antigens[1], and it seemed of considerable interest to determine whether, following severe X-ray damage, a similar stage occurred during which tolerance could be induced by appropriate antigenic stimulation. As X-ray damage is followed by rapid proliferation and differentiation of mesenchymal cells, be they the animal's own or bone-marrow cells grafted from a normal donor, it seemed possible that there might be a stage during which potential antibody-producing cells could be modified by contact with antigen and rendered immunologically tolerant.

Numerous workers, including Simonsen[2] and Nossal[3,4], have shown that the repeated injection of large amounts of foreign erythrocytes into embryos or neonates is followed by immunological tolerance. Accordingly, in the first series of experiments here reported, adult male *C3H* mice (bred by brother-sister matings for over forty generations) were exposed to 850 r. of whole-body irradiation, and 1–4 hr. later were given intravenous injections of isologous bone marrow. The bone marrow from six bones of one normal adult male donor was injected into each mouse. On the day following irradiation, and twice per week for four weeks during the recovery phase, the mice received intraperitoneal injections of 0·1 ml. of 20 per cent (packed cell volume) washed rat erythrocytes suspended in physiological saline. Normal adult *C3H* mice given a similar course of injections served as controls. One week after the last injection, the mice were bled, and the hæmagglutinin titre of the sera against rat cells determined. While the titre of one of the irradiated animals was much lower than those of the controls, it is clear from Table 1 that no immunological tolerance had resulted.

Table 1. Antibody Production in Lethally Irradiated Mice

Lethally irradiated bone marrow grafted mice (serum agglutinin titres)	Normal mice (serum agglutinin titres)
10,000	10,000
10,000	10,000
10,000	10,000
10,000	10,000
10,000	10,000
600	>10,000

Similarly, when adult mice were sublethally irradiated with 600 r., and injected with rat erythrocytes twice weekly for four weeks, all animals developed high titres of rat erythrocyte agglutinin. Next, the possibility that immature animals X-irradiated just after the end of the 'critical period'[2] for the induction of tolerance might be rendered tolerant by antigenic stimulation was explored. Day-old mice were given 500–700 r. of whole-body X-irradiation, and were afterwards injected twice weekly with 0·1 ml. of 20 per cent rat erythrocytes for four weeks. One week later, the agglutinin titre of their sera was determined. In three experiments out of four, all mice had high agglutinin titres. In the fourth experiment, similar in design to the other three, half the recipients had very low titres when compared with non-irradiated control mice given similar injections. However, even in this group the suppression of the immune response was temporary, and had almost disappeared when the mice were given two challenge injections of erythrocytes three months later.

Finally, attempts were made to save lethally irradiated adult mice with grafts of embryonic hæmopoietic tissue and to induce tolerance in this grafted tissue by antigenic stimulation. Attempts to use embryonic liver to save lethally irradiated animals were unsuccessful. Jacobson[5] has reported that about 30 per cent of lethally irradiated mice could be saved by injections of whole-embryo emulsion after irradiation. We were able to save about 20 per cent of our lethally irradiated animals by injection of 1·0 ml. of a mince prepared from 16–17 day-old mouse embryos. When these mice were injected with rat erythrocytes twice weekly for four weeks, the majority developed rat erythrocytes agglutinins. Most of the remainder developed high agglutinin titres when injected with further doses of rat erythrocytes three months later. Out of 15 animals examined, only one was still immunologically tolerant 20 weeks after irradiation, and it died shortly thereafter.

The failure to induce immunological tolerance in these circumstances is of considerable theoretical interest. It has been shown that mice lethally irradiated and saved with homologous bone marrow are thereby rendered immunologically tolerant of a skin graft from an animal of the donor strain[6]. During the very period when such a state of mutual tolerance is being developed, some cells, be it the proliferating grafted cells or the recovering host cells, evidently retain the capacity to produce circulating antibody to a heterologous antigen.

We wish to express our thanks to Sir Macfarlane Burnet for his interest in this work, and to the staff of the Peter MacCallum Cancer Clinic, especially Miss Betty Rose, for performing the irradiations. This work was aided by a grant from the National Health and Medical Research Council, Canberra.

Acid-Soluble Nucleotides from the Blood of Metamorphosing Salmon

In a search for possible precursors to the guanine that appears in large amounts in the skin of the salmon (*Salmo salar*) at the transformation from parr into smolt, blood samples from fishes in different stages of metamorphosis were collected and subjected to ion-exchange chromatography. The blood samples were obtained by cutting the tails of a number of fishes (as nearly equal in size as possible) and collecting the blood in a vessel cooled by a mixture of acetone and 'dry ice'. The frozen samples were extracted with 0·6 *N* and 0·3 *N* perchloric acid, neutralized by potassium hydroxide, and put on a 'Dowex 1' × 2 column in the formate form. The various fractions were eluted by the gradient elution technique of Hurlbert and his co-workers[1], as modified by Schmitz[2]. Extinction values of each fraction were read at 260 and 280 mμ in a Beckman spectrophotometer model *DU*. The various components were identified by their characteristic 260/280 mμ ratios[3], by their positions in the chromatogram, and by their ultra-violet absorption curves. For further analysis appropriate fractions from the peaks in the chromatogram were pooled, desalted by passing through a 'Dowex 50' column, evacuated to dryness at 20° C. and finally dissolved in a small volume of distilled water. Using the millimolar extinction coefficients given by Hurlbert and co-workers[1] the various compounds were estimated quantitatively. Base–ribose-phosphate ratios were based upon measurements of ultra-violet extinction values, analysis of total and acid-labile phosphate by the method of Berenblum and Chain[4], and analysis of ribose with the orcinol – hydrochloric acid method as modified by Hurlbert *et al.*[1].

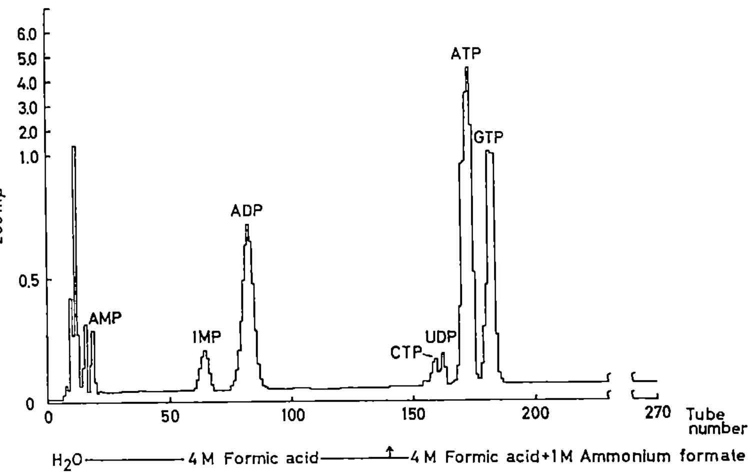

Fig. 1. Ion-exchange chromatogram of the acid-soluble nucleotides in the blood of metamorphosing salmon, taken during the pre-metamorphosis period (see text). 'Dowex 1' × 2 (200–400 mesh) column in the formate form, 0·9 cm. × 13 cm. Mixing volume, 250 ml.; flow-rate, 0·4 ml./min. Fraction volume, 5–4 ml. Key: AMP, adenosine monophosphate; IMP, inosine monophosphate; ADP, adenosine diphosphate; UDP, uridine diphosphate; ATP, adenosine triphosphate; CTP, cytidine triphosphate; GTP, guanosine triphosphate

It is apparent that with respect to nucleotide content of the blood, metamorphosis can be divided into three time-periods. The first, or pre-metamorphosis period, is dominated by a high guanosine triphosphate

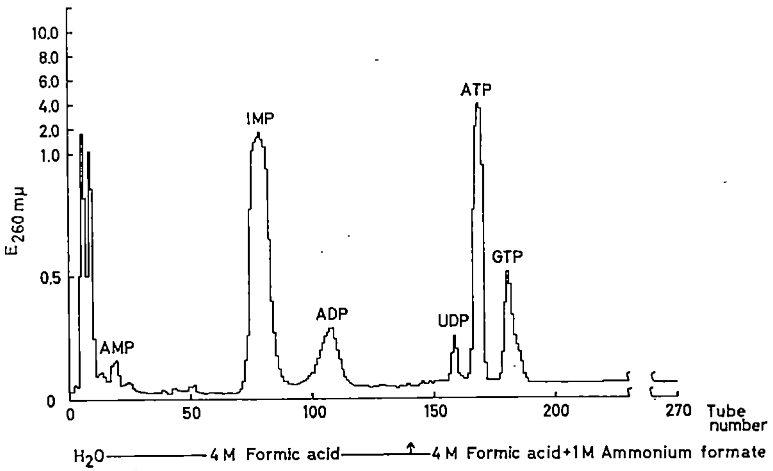

Fig. 2. Ion-exchange chromatogram of the acid-soluble nucleotides in the blood of metamorphosing salmon, taken during the metamorphosis period (see text). Conditions and key as for Fig. 1

and a low inosine monophosphate content (Fig. 1). During this period there is no pronounced deposition of guanine in the skin. The next period, the metamorphosis period, is characterized by a high inosine monophosphate content of the blood, a high rate of guanine deposition, and a reduced guanosine triphosphate content of the blood (Fig. 2). In the third or post-metamorphosis period the inosine monophosphate content of the blood has also been reduced to a low level so that, with respect to nucleotide content, the blood is quite comparable with that of a non-metamorphosing salmon.

A comparison with values for animal tissues given in the literature[5,6] indicates that guanosine triphosphate occurs in remarkably high concentrations in the blood of the salmon, especially during the pre-metamorphosis period, when it amounts to about 30 per cent of the adenosine triphosphate value. But also during non-metamorphosing periods the guanosine triphosphate content of the blood of salmon is high as compared with, for example, muscle tissues, which have been reported by Bergkvist and Deutsch[5] to contain guanosine triphosphate in amounts of about 1 per cent of that of adenosine triphosphate. The corresponding figure for the blood of salmon is about 10 per cent.

Full details of this investigation will be published elsewhere.

Toxic Effects produced by Pyrimethamine in Chickens and their Antagonism by Folic Acid

PYRIMETHAMINE, a folic acid antagonist, has been shown to potentiate the activity of sulphadimidine and sulphaquinoxaline against cæcal coccidiosis in chickens (ref. 1 and Ball, S. J., private communication). During our investigation of this combination, the decreased growth-rate and anæmia observed in Rhode Island × Light Sussex chickens fed for 28 days on an all-mash diet containing 20 p.p.m. of pyrimethamine, appeared to be controlled by a dose of 10 mgm./kgm. folic acid. The mean weight gain over the experimental period is shown in Table 1.

Table 1. MEAN WEIGHT GAIN, MEAN CELL VOLUME AND MEAN CORPUSCULAR HÆMOGLOBIN CONCENTRATION IN CHICKENS AFTER 21 DAYS

Pyrimethamine in diet (p.p.m.)	Folic acid injections (i.p.) (dose × 2 weekly)	Mean weight gain (gm.) ± S.E.	Heart blood					Liver
			Red blood cell count (× 10^6/mm.^{3})	Hæmatocrit (per cent)	Hæmoglobin (per cent)	M.C.V. (μ^3)	M.C.H. ($\mu\mu$gm.)	Mean total iron content (mgm. per cent) ± S.E.
0	—	241·2 ± 19·14	2·41	30	9·1	126	35	37·7 ± 2·2
	100 mgm./kgm.	227 ± 20·1	2·38	29	8·7	121	36	33·8 ± 3·5
20	—	145·0 ± 16·95	1·18	18	6·3	154	52	82·2 ± 14·8
	100 mgm./kgm.	233·0 ± 13·06	2·46	30	9·5	119	38	40·0 ± 5·0

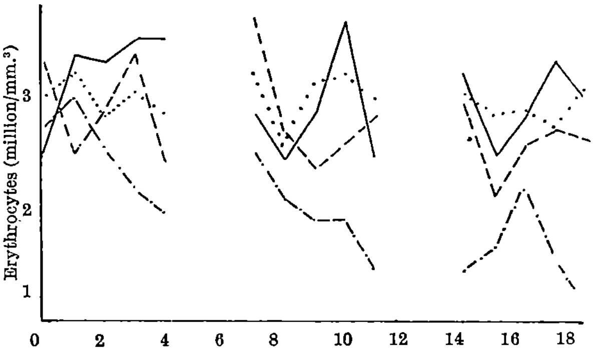

Fig. 1. ......, Control; —.—.—, pyrimethamine, 20 p.p.m.; ———, folic acid; ----, pyrimethamine 20 p.p.m. + folic acid

Daily erythrocyte counts were made in blood taken from the wing vein (Fig. 1). After 21 days the erythrocyte count, hæmatocrit and hæmoglobin concentration in the heart blood and the total liver iron content of each of the birds were measured (Table 1). Sections of liver, treated with potassium ferrocyanide, were examined for hæmosiderosis.

Pyrimethamine (20 p.p.m.) in the feed caused a significant depression of gain in weight ($P < 0.03$) and a macrocytic, hyperchromic type of anæmia. These effects were not present in the chicks receiving folic acid injections in addition to the pyrimethamine. The folic acid injections alone produced no effect on gain in weight or on the blood measurements.

There was a significant increase ($P < 0.05$) in the total iron content of the livers of the chicks (Table 1) receiving pyrimethamine only, and hæmosiderosis was noted in liver sections treated with potassium ferrocyanide, from the birds in this group. These latter observations suggest that a hæmolytic process, in addition to any effects produced on erythropoesis, is involved in the production of anæmia, a finding previously reported by Zach[2], who detected free hæmoglobin in the serum of rats receiving pyrimethamine.

From this work it appears that the toxic effects of pyrimethamine were caused by a state of folic acid deficiency, as they were controlled by the administration of folic acid.

Effects of Reserpine on Secretion from the Adrenal Medulla

It is a well-established fact that reserpine causes a depletion of catechol amines[1] [2] in various organs. Whether this depletion is due to a decreased rate of synthesis or to an increased rate of release from the storage sites has not been clearly shown.

Changes in the content of catechols in the blood after administration of reserpine have been reported by Muscholl and Vogt[3], who found in rabbits, using biossay, an increase in venous plasma adrenaline but no measurable change in noradrenaline. In contrast, Burger[4] reports in man a distinct fall in plasma noradrenaline and a slight fall in plasma adrenaline, as measured by a fluorimetric method.

In the experiments reported here the purpose has been to determine whether reserpine causes secretion of medullary hormones into the adrenal venous blood.

To cats of both sexes, weighing 3–4 kgm. and anæsthetized with 'Nembutal' (Abbott), given intraperitoneally, 3 mgm./kgm. reserpine ('Serpasil', Ciba) was administered intravenously. Collections of adrenal vein blood were made at intervals using a special shunt technique (Schapiro and Stjärne, to be published). The adrenal vein plasma and the organ extracts were assayed biologically (cat's blood pressure and hen's rectal cæcum).

Reserpine was found to cause a transitory fall in blood pressure in every experiment except one, in which both vagi had been cut and the carotid sinus denervated bilaterally. In this case a gradual pressor effect was observed, lasting for 20 min. with a maximum value 40 mm. mercury above the resting level.

In every experiment reserpine caused a well-marked increase in the secretion-rate of both adrenaline and noradrenaline. The increase was already present in the first collection period 10–15 min. after reserpine was given; it reached its maximum value 1½–2 hr. later (Fig. 1). The effect on noradrenaline secretion was consistently greater than that on adrenaline, noradrenaline making up 75–90 per cent of the total catechols released. The amount of noradrenaline recovered in the adrenal vein blood in some experiments is so large that it suggests an increased rate of resynthesis, at least initially (Table 1).

The results of our experiments suggest that reserpine causes a relatively selective mobilization of noradrenaline. This is in accordance with the results reported by Eränkö and Hopsu[5]. These workers have shown by histochemical methods in rats that reserpine causes typical secretory changes almost exclusively in the parts of the adrenal medulla containing noradrenaline. The initially increased resynthesis-rate observed by us during the first 2–3 hr. after the administration of reserpine is of special interest in view of reports (refs. 6 and 7 and Bygdeman, S., and von Euler, U. S., personal communication) showing that direct electrical stimulation of the splanchnic nerve causes an acceleration of synthesis. However, the dose of reserpine used by us is known to cause an almost complete emptying of the adrenal medulla in 16–24 hr. Thus it seems clear that in the long run resynthesis cannot keep pace with secretion.

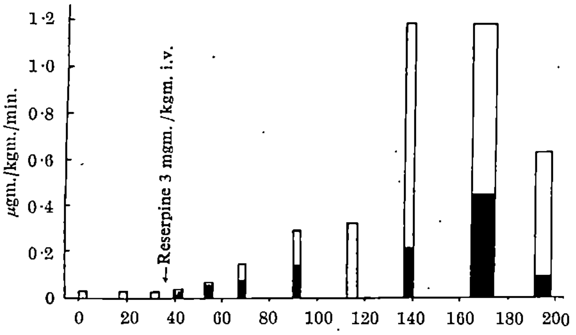

Fig. 1. Secretion of adrenaline and noradrenaline after the intravenous administration of 3 mgm./kgm. reserpine. White, noradrenaline; black, adrenaline

Table 1. Adrenaline and Noradrenaline in the Adrenal Medulla after Experiment 10, as compared to the Recovery in the Adrenal Vein Plasma after Reserpine

The calculation of the output is based on the assumption that during each shunt period the secretion can be represented by the average of the collection period immediately before and after it

Weight of left adrenal gland, 295 mgm.	Adrenaline (μgm.)	Noradrenaline (μgm.)
Content of left adrenal after the experiment (a)	62	15
Recovery in adrenal vein blood after reserpine (b)	91	282
Total amount recovered (a + b)	153	297

Other experiments of ours (in preparation) as well as by others[1,2] [8] indicate that the effect of reserpine on the adrenal medulla is to a large extent dependent on the innervation of the gland being intact.

This investigation has been supported by a grant to one of us (L. S.) from Svenska Nationalföreningen mot Tuberkulos och andra Folksjukdomar.

Behaviour of 19-nor-Progesterone and 19-nor-Ethinyltestosterone in the Liver of the Guinea Pig

The antiœstrogenic properties of 9-α-fluoro-11-β-hydroxyprogesterone are superior to those of 11-β-hydroxyprogesterone[1]. The halogenated compound resists inactivation in the liver[2]. This resistance has been corroborated in a new set of experiments (Table 1, *A*, *B* and *C*), from which it is evident that a given amount absorbed from an intrasplenic pellet (*B*) is less active than when absorbed from a subcutaneous one (*A*). There is no doubt, however, as to resistance of the halogenated compound in the liver (compare *B* and *C* with I*b*). Thus greater activity, namely, enhanced antifibromatogenic, antihysterotrophic and antiluteinizing properties of the halogenated, as compared with the non-halogenated

Table 1. EXPERIMENTS ON EIGHTY-EIGHT CASTRATED GUINEA PIGS RECEIVING DURING THREE MONTHS ŒSTRADIOL ABSORBED FROM SUBCUTANEOUSLY IMPLANTED PELLETS, AND VARIOUS ANTIŒSTROGENIC STEROIDS ABSORBED FROM SUBCUTANEOUS OR INTRASPLENIC PELLETS

* Taken for comparison from ref. 5*a*. † See ref. 1*b*.

compound, could be explained, in part at least, by a different behaviour of the two compounds in the liver.

The question now arises whether the same is true for 19-nor compounds. The antiœstrogenic activity of 19-nor-progesterone (19-nor-P) is (like its progestational potency[3]) much greater than that of progesterone[4]. It is the same with 19-nor-ethinyltestosterone (19-nor-ET)[5], and 19-nor derivatives of testosterone compared with the natural androstenes[6].

We have now studied the antifibromatogenic action of progesterone and 19-nor-progesterone absorbed from pellets implanted in the spleen. The results show that both substances are undoubtedly inactivated in the liver (Table 1; for details see Fig. 1). With intrasplenic pellets of either progesterone or 19-nor-progesterone (I*b* and II*b*) the fibrous tumoral effect is as great as in animals receiving œstrogen only; similar quantities absorbed from subcutaneous pellets (I*a* and II*a*) produce a very notable antifibromatogenic effect. The same holds for the comparative antihysterotrophic effects with subcutaneous and intrasplenic pellets.

One might argue that in II*b*, with intrasplenic pellets of 19-nor-progesterone, the average quantity absorbed per day was somewhat smaller than in II*a* with subcutaneous pellets. But this argument is invalidated by the fact that, even with 9 μgm./day of 19-nor-progesterone absorbed from intrasplenic pellets (II*c*), no definite antifibromatogenic effect is obtained which would be comparable to that obtained with a quantity five or six times smaller when absorbed from subcutaneous pellets (II*a*). Indeed, the fibrous tumoral effect in II*c* was not so great as in I*b* and II*b*. But this insignificant antitumorigenic effect was evidently due to very small quantities of the highly active 19-nor-progesterone which escape intrahepatic inactivation; the same happens even with the less-active progesterone when absorbed from intrasplenic pellets[7].

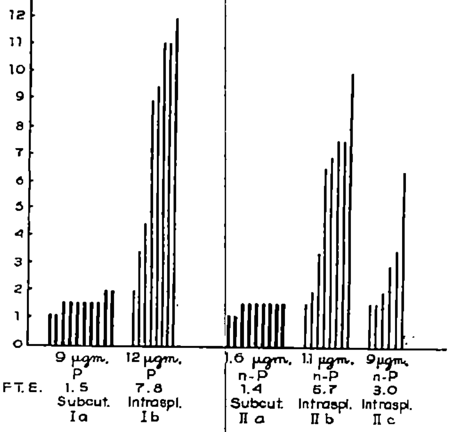

Fig. 1. Fibrous tumoral effect (FTE) in arbitrary units in guinea pigs with subcutaneously implanted pellets of œstradiol. Thick lines, animals with an additional subcutaneous pellet of progesterone or 19-nor-progesterone. Thin lines, animals with an additional intrasplenic pellet of progesterone or 19-nor-progesterone. When absorbed from the spleen both progesterone and 19-nor-progesterone lose their antifibromatogenic activity

Experiments with 19-nor-ethinyltestosterone are also of interest. It is known that progestational action can be obtained with ethinyltestosterone when given by mouth; this presupposes good resistance in the liver. The antifibromatogenic potency of ethinyltestosterone is inferior to that of progesterone and reaches only that of testosterone[8]; but 19-nor-ethinyltestosterone is several times as potent as ethinyltestosterone[1c, 5b]. How will 19-nor-ethinyltestosterone behave when absorbed from an intrasplenic pellet? A comparison between III*a* and III*b* (Table 1) shows that there is no difference in the results obtained with subcutaneous and intrasplenic pellets of 19-nor-ethinyltestosterone. Thus the latter resists inactivation in the liver. In other words, the 19-nor configuration is of no consequence with regard to resistance in the liver (19-nor-ethinyltestosterone), and neither is it of any consequence as to non-resistance (19-nor-progesterone).

Thanks are due to Messrs. Syntex, Mexico, for progesterone and 19-nor-progesterone; to Prof. Carl Djerassi, Waine University, Detroit, for 19-nor-ethinyltestosterone.

Conditions which eliminate Inflammation to Homografts in Rabbits

THE stimulus for production of a sterile cellular infiltrate, principally lymphocytic, in and about a homograft remains obscure. Methods whereby this inflammatory reaction may be eliminated are worthy of consideration with the view of successful homografting between members of genetically impure strains.

Previous studies using musculofascial transplants of erector spinæ of rabbits permitted accurate distinctions to be made by ordinary histological methods between autografts and homografts[1]. Microscopic examination two weeks after implantation showed that both types of grafts underwent similar sequences of degeneration, resorption and organization, but in the homograft inflammation was superimposed upon the repairative matrix of the musculofascial zone. Angiitis involving the newly formed channels was a frequent feature of the inflammatory reaction.

Further experiments have shown that the classical inflammatory aspects of host–homograft interactions may be eliminated by several conditions. One condition was by reduction of 'viability' of tissues of the musculofascial graft by exposure to extremes of heat, cold or X-irradiation prior to implantation[2,3]. Both types of grafts so treated elicited a sluggish fibro-collagenous response by the host. Grafts studied following less extreme exposure to temperature and X-irradiation showed that the degree of admixture of proliferating cells of the graft with those of the host seemed to determine the magnitude of the inflammatory reaction in homografts.

A second condition for the elimination of inflammation in homografts required grafting between parabionts in the post-parabiotic period. Rabbits surgically united by the ears developed a cross-circulation lasting between 7 and 13 days after anastomosis[4]. The cessation of the cross-circulation seemed to be related to the development of inflammation at the surgical plane of anastomosis between the animals. Joining rabbit parabionts a second time failed to reproduce sequences of healing noted at primary junctions. This was in accord with the "second set rejection phenomenon"[5]. Microscopic study of cross-homografts between parabiotic partners following one and two periods of parabiosis showed two types of tissue reaction equally distributed between the two groups of parabionts[6]. The first type consisted of a fibro-collagenous encapsulation of the graft by the host in the absence of vascular penetration. Inflammation did not develop. The second type of post-parabiotic modification was similar to the first, with the exception that a peculiar angiomatous vascular plexus of capillaries arising from the host grew beneath the fascia of the homograft. Inflammation was again absent.

The third condition required cross-transfusion. Since a transient cross-circulation was a conspicuous feature of the primary healing between parabionts, cross-transfusions of whole blood, controlled in quantity, were done between pairs of rabbits[7]. This eliminated all factors involved in parabiosis except exchange of blood. The microscopic study of cross-homografts following cross-transfusions showed a vascularizing stromal penetration identical to the second type of host–homograft interaction following parabiosis. Inflammation was absent.

A fourth condition required for elimination of inflammation in homografts was the pregnant state. Gravid rabbits (13–15 days of gestation) were cross-grafted with males and non-pregnant females of the same species[8]. Autografts were also implanted. Each pregnant host reacted in the same way to autografts and homografts. Both types of grafts showed the usual sequences of degeneration, absorption and organization in the absence of inflammation characteristic of host–autograft reactions. It appeared that pregnancy lessened the capacity of the animal to react against grafts of normal homologous tissues.

These observations have indicated that investigation of the means by which the inflammatory aspects of host–homograft interactions are eliminated may offer clues to the solution of the problem of successful homografting.

This work has received generous support from the National Heart Institute (*H*-1630, *H*-3215), National Institutes of Health, United States Public Health Service; the Muscular Dystrophy Associations of America, Inc., and the Otho S.A. Sprague Memorial Institute.

Sarcoma in Albino Rats treated during the Embryonic Stage with Rous Virus

THE cystic-hæmorrhagic disease[1,2] of albino rats caused by the Rous sarcoma virus indicates that the rats are susceptible to this virus. Starting from the well-known work of Duran-Reynals[3,4] I have attempted to reduce the susceptibility of the rats to the Rous virus by treating embryos with specific antibodies. The technique of inoculation has been described elsewhere[5].

0·1–0·15 ml. 50 per cent homogenate of the Rous sarcoma was injected subcutaneously into each embryo of four laparotomized pregnant white rats. Concurrently 0·2–0·25 ml. antiserum of rabbits repeatedly immunized with the homogenate of the Rous sarcoma was injected intraperitoneally into the same embryos. Of the four pregnant rats, two aborted, one gave birth to and suffocated its litter, and only one bore successfully five rats, of which two were suffocated.

In two of the three surviving rats small, very slowly growing cysts developed one month after the inoculation, but these regressed in course of time; 6 and 7 months thereafter sarcomata developed in these two rats. In one of them sarcoma appeared on the dorsal side of the neck, precisely at the site of primary infection with the Rous virus. The tumour attained the size of an apricot; histologically it was a sarcoma with a significant polymorphism resembling the Rous sarcoma. In the tissue spindle-like cells predominated, along with rounded cells and much mucopolysaccharide. In the second rat a 2-cm. sarcoma with spindle-like cells developed on the cheek.

The sarcoma was minced with scissors and subcultured in rats of various ages. It grew well in new-born rats, and within 20–25 days reached a large size, causing death in some animals. In young rats (50–60 gm.) growth of the tumour proceeded more slowly; it attained a large size in some of them. The weight of the tumour in such cases reached the weight of the rat itself, although in some individuals growth was poor, being followed by regression. In adult rats weighing 120–150 gm. the tumour reached the size of a bean and was then resorbed. In new-born and young rats the tumour grew on the second and third passages as well. Here the tumours were characterized histologically by appreciable homogeneity, being composed exclusively of spindle-shaped cells containing less mucopolysaccharide and being more solid than the initial tumour. The inoculation of minced rat sarcomata to chickens was unsuccessful. It is possible that the Rous virus is present in the rat tumours in the masked form.

It might seem that the inhibition of the pathogenic effect of the Rous virus by antiserum led to the development of sarcomata instead of the typical cystic-hæmorrhagic disease in rats infected during the embryonic period. Yet in one of the rats inoculated with the Rous virus during the prenatal period, without additional treatment with antiserum, a slowly growing cyst developed, which, seven months afterwards, was replaced by a huge sarcoma.

These experiments were carried out on rats of a stock free from spontaneous malignant tumours.

Hydrogen Peroxide Ingestion and the Growth of Rats

SEVERAL recent communications have dealt with the capacity of ingested hydrogen peroxide to affect the regression of implanted tumours in rats. Holman[1] has claimed that a 0·45 per cent solution of hydrogen peroxide given to rats in lieu of tap-water caused regression of certain tumours; the opposite conclusion has been stated by Green and Westrop[2] and by Ghadially and Wiseman[3]. Accordingly, it seemed important to determine the effect of hydrogen peroxide on normal rats.

In one experiment, two groups of weanling male rats of the Osborne-Mendel strain developed at this Station were given a commercial dog food meal, and either tap-water or 0·45 per cent hydrogen peroxide *ad libitum* for a three-week period. During the test period, the animals on tap-water consumed an average of 544 ml. each, whereas those on peroxide averaged only 282 ml. each. The decreased amount of liquid intake was reflected in the total body-weight; 156 gm. for those on tap-water against 108 gm. for those on peroxide. No differences in the fresh weight of the testes, kidneys or spleen of the two groups were found.

In order to equalize any effects of limited intake of liquid, another group of male weanling rats was offered 0·45 per cent hydrogen peroxide in lieu of tap-water for a three-week period. Daily consumption was recorded, and a comparable group of male weanlings was given an amount of tap-water equal to the liquid consumed by the animals on peroxide. This regimen was also continued for a three-week period. It was observed that the group of rats on tap-water were continually seeking water, whereas those on peroxide did not act in a similar manner. The average body-weight was 116 gm. for those on peroxide and 104 gm. for those on tap-water. An attempt was made to see if ingestion of peroxide affected the fresh weight of some of the internal organs. Calculated in terms of percentage of body-weight, no important differences were found in the testes, kidneys, spleen or heart. The dry weights of these same tissues, calculated as percentage of body-weight, also failed to show differences.

Three weanling females were placed on a 0·45 per cent hydrogen peroxide regimen and maintained on it for five months. They were then given tap-water instead and were mated with normal males. Normal litters were produced. Six male litter mates were divided into two equal groups: one received peroxide while the other received tap-water. The animals were maintained on their respective regimens for nine months. The only noticeable effect was a difference in body-weight; an average of 521 gm. for those on tap-water against 411 gm. for those on peroxide. Three older males with an average weight of 600 gm. were given 0·45 per cent hydrogen peroxide for six weeks. At that time their average weight had fallen to 511 gm. They were then given tap-water and within two weeks had regained the lost weight.

Weanling rats offered the hydrogen peroxide *ad libitum* failed to gain weight normally. Although it had previously been shown that larger rats fed peroxide failed to gain weight normally[3], this phenomenon has not previously been noted for weanlings. Ghadially and Wiseman[3] attributed the loss of weight to diminished food intake; but, as noted above, this result may also be caused by a diminished liquid intake. Furthermore, long-term feeding of peroxide did not appear to affect reproduction in female rats.

Role of Hypersensitivity in Experimental Staphylococcal Infection

It was shown previously[1] that a mild staphylococcal infection in rabbits can produce a state of both skin and systemic delayed hypersensitivity with some signs of immunity. Antitoxin formation, increased bactericidal activity of leucocytes and increased clearing of injected staphylococci from the blood and organs was found. Yet after a challenge with intravenous staphylococcal infection these rabbits died more rapidly and in larger numbers than normal controls. It has been also reported[2] that after production of hypersensitivity of the delayed type in guinea pigs using immunization with staphylococcal vaccine in Freund-type adjuvant, more numerous and larger abscesses are formed during the following infection; this conclusion has been given without detailed experimental results. In the experiments presented here an attempt was made to transfer to normal recipients this state of lowered resistance to staphylococcal re-infection passively, using cells of hypersensitive donors.

The desired state of hypersensitivity was produced in chinchilla rabbits by repeated intradermal and intravenous infections with small doses of staphylococci. Animals were selected after some weeks of treatment according to the intensity of skin reactions to diluted staphylococcal toxoid and vaccine given intradermally; in addition, α-antitoxin and agglutinin blood titres were determined. Spleen cells or peritoneal exudate cells (saline, 4 hr.) were transferred intraperitoneally to normal recipient rabbits; 200–300 million living cells were used. The exudate consisted of 10–30 per cent lymphocytes, 70–90 per cent polymorphonuclears and 5–10 per cent macrophages.

Normal rabbits with negative skin tests and without ascertainable antibodies were used as recipients and control donors. On the day following transfer the recipients were tested with staphylococcal toxoid and vaccine and reactions were recorded after ½, 2, 6, 24 and 48 hr. Following the last reading the animals were infected intravenously with 20 million micro-organisms of a virulent staphylococcal strain. Bacteriæmia was studied during infection and in some experiments the number of micro-organisms in different organs was also determined. Values of bacteriæmia for the last 24 hr. before death are not given.

As expected[3], transfer of cells resulted in skin hypersensitivity of the delayed type in the recipients. The results of staphylococcal infection in the experimental and control groups of rabbits are summarized in Table 1. It is evident that increased susceptibility to staphylococcal infection can be transferred with living cells from hypersensitive animals, while killed cells (65° C. for 30 min.) and cells from normal rabbits are without effect.

Table 1. Results of Staphylococcal Infection in Different Experimental Groups

	No. of rabbits	Deaths	Survivals	Deaths (per cent)
Hypersensitive rabbits	21	17	4	81
Recipients of hypersensitive cells	38	27	11	71
Recipients of killed hypersensitive cells	19	5	14	26
Recipients of normal cells	12	3	9	25
Normal rabbits	24	5	19	21

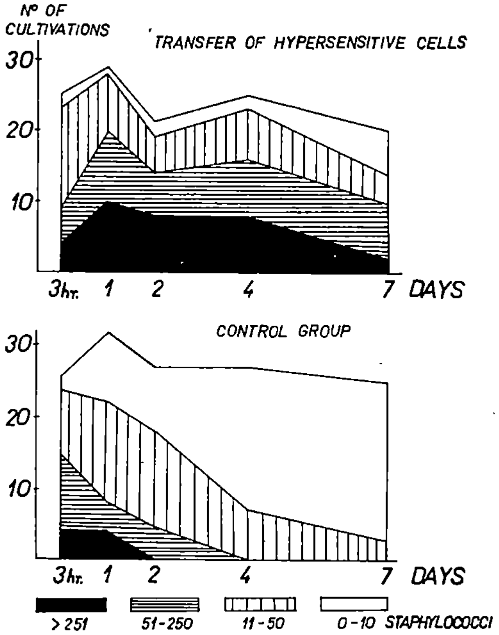

Fig. 1. Numbers of staphylococci cultivated from 1 cm.^{3} of blood during intravenous infection in rabbits passively sensitized with cells and in control rabbits

The bacteriæmia in rabbits previously sensitized with cells of hypersensitive rabbits remains high in the course of infection, while the bacteriæmia in control groups (normal rabbits, rabbits receiving normal cells or killed hypersensitive cells) declines progressively (Fig. 1). More micro-organisms are also found in organs. Cultivation from animals killed 48 hr. after infection gave the following average values per 100 mgm. organ-weight: in rabbits passively sensitized with cells—liver, 147; spleen, 156; lungs, 139; in control rabbits—liver, 3; spleen, 3·5; lungs, 4·5 micro-organisms.

The above results show that the state of increased susceptibility to staphylococcal infection can be transferred to normal recipient rabbits by means of living cells together with the delayed hypersensitivity to staphylococcal antigens. There is no direct evidence that there is a causal relationship between these two phenomena. There is no negative evidence, however, and no other reasonable interpretation can be given. It seems probable that the influence of hypersensitivity on the course of staphylococcal infection is due to changes (injury of cells, inflammation, etc.) that occur in tissues of sensitized animals after contact with the antigens of the infecting micro-organism; these changes may provide better conditions for the development of staphylococcal infection.

Plasma Cells and Tumour Growth

Growth and regression of a tumour in experimental animals are known to be accompanied by various changes in the organs of the host, especially in the lymph nodes and spleen. Although there is a close association between immunity to a transplantable tumour and presence of local cellular infiltrations of, say, lymphocytes and plasma cells, there has been a wide diversity of opinion as to the specific cell or cells involved.

It is generally agreed that homografts of normal and tumour tissues are destroyed by a 'specific immune' reaction, but this still lacks the confirmation of direct demonstration of the presence of any antibody. Recent work has shown that plasma cells are involved in the production of antibody against bacterial, viral and other foreign protein antigens[1]. Several workers have also observed plasma-cell development in the host, following tumour[2] and normal tissue homografts[3].

I have approached the problem from a different angle, namely, by demonstrating plasma-cellular reaction in the tissues of the host, which may be considered as a pointer to the immunological changes taking place. A detailed histological and cytological study was made in rats to observe the local and remote reactions in the host, following transplanted and induced tumours, during the stage of progressive growth and regression, with special reference to the plasma-cell equipment.

Tuck male albino rats were employed throughout. Transplantable *Rd*/3 rat sarcoma (originally induced by 1 : 2 : 5 : 6-dibenzanthracene) and Walker carcinoma were used. Tumours were implanted subcutaneously into the right flank. Induced tumours were produced by subcutaneous injection of 1 : 2 : 5 : 6-dibenzanthracene in arachis oil. Tumour (*Rd*/3 and Walker) inhibition and regression were induced by intraperitoneal injection of 1 : 2 : 5 : 6-dibenzanthracene (2 mgm./100 gm. of body-weight) suspended in 0·2 per cent 'Teepol'. Animals were killed at different stages of tumour growth, inhibition and regression. Histological sections and smear preparations were made from these tumours and different organs, and stained with hæmatoxylin and eosin and Unna-Pappenheim (methyl-green and pyronin). The amount of plasma cells was estimated from these preparations.

In the normal rats, the lymph nodes, specially the axillary and para-aortic (lumbar) and the spleen contain very few plasma cells, mostly mature in type, in the medulla and red-pulp respectively. The main cellular constituents are the lymphocytes.

During the progressive growth of the transplanted tumour (*Rd*/3 and Walker), the draining lymph nodes, namely, the right axillary and para-aortic and the spleen are increased in weight. Some of these enlarged lymph nodes show hæmo-lymph node formation. Histologically, in the lymph node, the medulla is increased in size, replacing the cortical lymphoid tissue and the sinuses are dilated. The broad medullary cords are crowded with proliferated reticulum cells and plasma cells (immature and mature), accompanied by diminution of lymphocytes. Russell-body cells are also found. Mitoses are frequent. No increase of plasma cells is seen in the cortex. In the hæmo-lymph nodes, large numbers of erythrocytes are found in the sinuses and many free macrophages show erythro-phagocytosis. In the spleen, the red pulp is highly cellular and shows proliferation of reticulum cells and increased number of immature and mature plasma cells, specially around the trabeculæ. The Malpighian follicles are not much affected and no increase of plasma cells are found. Transitions from reticulum cells to mature plasma cells are seen.

There is a significantly constant relation between the amount of plasma-cell response, weight of these organs and of the tumour. No definite relation between plasma-cell increase, hæmo-lymph node and metastasis formation is found. Moreover, the lymph nodes having secondary metastases show a marked diminution of plasma-cell reaction. A similar but less marked change is observed with tumours induced by dibenzanthracene.

The local reaction of the host around the tumour during its progressive growth is slight and the cellular infiltration is scanty, consisting of lymphocytes, macrophages, plasma cells and a few polymorphonuclear neutrophils, embedded in a connective tissue. Experimentally induced tumour inhibition and regression are regularly associated with an increased local reaction of the host around the tumour, consisting of accumulation of large numbers of plasma cells, without any appreciable alteration of the lymphocytic infiltration. This local plasma-cell accumulation is more numerous about the nodules of viable tumour cells, and in a few instances appeared to have invaded them, resulting in their degeneration and disappearance. When the tumour cells are no longer present, the local reaction subsides and the plasma-cell accumulation diminishes.

Following induced regression of the transplanted tumour, the animal becomes resistant to a subsequent challenge with the same tumour at a different site. Presence of living tumour cells is essential for this plasma-cellular response. Heat-killed tumour graft, which is no longer capable of stimulating this response, fails to render the host resistant to a subsequent inoculation with living tumour cells. Such a phenomenon is strongly suggestive of the presence of a circulating antibody.

These findings suggest that the increased response of plasma cells is the morphological manifestation of a systemic immune reaction to circulating antigen(s), which leave the graft, and reach the regional lymph nodes and spleen, where they excite this reaction, like any other antigens, and that plasma cells are involved in the production of antibodies. Other elements do not appear to have the same significance. Attempts to identify the antigenic substance in the tumour have so far been inconclusive.

Recent study of the nucleic acid content also supports the participation of draining lymph nodes in the formation of antibody against the transplanted tumour, and ribonucleic acid in these organs has been found to be increased, suggesting synthesis of protein[4]. Such enlarged lymph nodes have also been shown to take part in the immunological response conferring passive tumour transplantation immunity in secondary hosts[1,5]. Using the Schultz–Dale technique, it has been demonstrated that the presence of antibody in the host is the basic mechanism involved in this passive tumour transplantation immunity[1]. Further, the growth of the tumour cells is inhibited by treating them *in vitro* with excess of splenic and lymph-nodal cells from tumour-bearing animals. The only histologically demonstrable change in these organs taking part in the immunological phenomenon is the increased accumulation of plasma cells.

Cortisone, which abrogates the resistance to homo- and heterologous tumour grafts, inhibits this plasma-cell response in these organs. But once the immune reaction is established, cortisone fails to interfere with it, in spite of damage to the lymphocytes. This shows that cortisone strongly depresses antibody formation to antigens of the transplanted tumour tissue, by inhibiting plasma-cell development. These findings further show a constant relation between the plasma-cellular reaction and tumour resistance, which cannot be explained in terms of lymphocytes.

The conclusion which can be drawn from this study is that during reaction to bacterial and other foreign protein antigens, tumour and normal tissue-grafts, the plasma-cellular response may be considered as a pointer to the immunological change taking place. Judged by the plasma-cellular reaction, transplantation immunity to tumour and normal tissues conforms with the immune state generated by bacterial and other foreign protein antigens.

This work was carried out in the Cancer Research Unit, University of Sheffield, and I am indebted to Prof. H. N. Green for his interest and helpful discussions.

Resistance to Flow in Vascular Beds

Dr. S. D. Carlill[1] has attacked the standard concept of resistance to flow (R) as the ratio of the driving force (the pressure drop P across the bed) to the flow F, and advocates that the 'dynamic resistance', that is, the differential dP/dF be substituted. His argument seems to assume what he is trying to prove.

Derived measures, or indices, depend for their usefulness on concepts that may underlie them. The standard measure of electrical resistance, in ohms, is used because we know that the applied potential difference plays a primary part in determining the current. Use of the ratio of voltage drop to current then allows us to remove the influence of this primary factor at the outset, and to concentrate on the other factors that determine the flow in a particular conductor. These factors are the specific conductivity of the material of the conductor, and its 'geometrical factor', that is, length over cross-sectional area.

The usefulness of the ohm is in no way dependent upon linearity between applied voltage and current. In modern electronics, perhaps the majority of the circuit components are non-linear (do not obey Ohm's law), yet we still use the ohmic resistance. We recognize, however, that the resistance of these components is not independent of the applied voltage, or of the current flowing. After all, Ohm's law itsel has to make the condition that the resistance of a given conductor is constant, independent of the applied voltage, only if the temperature is kep constant (and actually the temperature must depen on the current flowing). By using the ratio of potential drop to current, that is, the ohmic resistance we can study how the ratio depends upon othe factors, including the voltage or current in non-linear cases.

With 'Newtonian' fluids flowing in cylindrical non distensible tubes, Poiseuille's law applies. This is best written :

$$F = P \times \left(\frac{\pi}{8}\right) \times \left(\frac{1}{\eta}\right) \times \left(\frac{r^4}{l}\right) \qquad (1$$

$$= P \times (N) \times (V) \times (G) \qquad (2)$$

where F is the flow, P the drop in pressure, (N) is the 'numerical factor', occurring in the integration of Hagen's theoretical treatment, (V) is the 'viscosity factor', and (G) is the 'geometrical factor' (r = radius, l = length of tube). On the standard definition, the resistance R is given by :

$$R = \frac{P}{F} = \frac{1}{(N) \times (V) \times (G)} \qquad (3)$$

In the case cited, R is independent of P and of F.

When the flow-pressure curves are non-linear, as they are with blood flowing in vascular beds[2], we can legitimately consider that equation (3) still applies under any given condition of pressure and flow, but either the viscosity factor (V) or the geometric factor (G) is not constant but depends upon the pressure and the flow. If the vessels are distensible, their 'geometrical factor' (G) alters with the 'transmural pressure' of each of the vessels. If the fluid is non-Newtonian, having an 'anomalous viscosity', the viscosity factor (V) will depend on the rate of flow. Resistance of a vascular bed, therefore, depends on the pressure (not primarily upon the driving pressure, but on the 'transmural pressure'—for example, a rise of venous pressure greatly affects the resistance even if the driving pressure is kept constant[3]). The curves of resistance versus pressure are much as shown in Dr. Carlill's Fig. 1, and this has been pointed out many times by us and by others[1].

The point is that, in spite of this consideration, the resistance to flow, as the ratio of P/F, still tells us what the product of geometrical factor (G) and the viscosity factor (V) is for that set of conditions of pressure and flow. If, as fortunately it turns out to be, the viscosity factor has not changed appreciably[4], the change in the geometrical factor can be deduced from the change of resistance. If the resistance has increased, the vessels have become 'narrower'; if it has decreased the vessels have 'widened'. This is a big step in clarification, even though the question remains as to why the calibre of the vessels has changed. Was it because of a change in transmural pressure, or was it due to an 'active vasoconstriction' or 'vasodilation' (that is, due to contraction of the smooth muscle of the wall)? Often this question can be decided, in other cases not. For example, if the resistance has increased but the pressures has not changed or has risen, this must have been active vasoconstriction, for the distensible vessels would passively decrease in size only if pressures fell. Thus the use of 'resistance to flow' greatly clarifies such problems.

Let us now consider Dr. Carlill's substitute for the conventional 'resistance', the 'dynamic resistance' dP/dF, derived from the slope of the flow-pressure curve. The 'instantaneous resistance' or its reciprocal, the 'transconductance', is, of course, familiar in electronics, where the slope of the characteristic for a given set of operating voltages, etc., is used in calculating amplification factors and the like. There will be a set of problems in hæmodynamics where the analogous 'dynamic resistance' is useful. These are those where the rate of change of flow in a vascular bed with change of blood pressure is relevant, for example, problems of control of circulation and its homœostasis. In our laboratory we have recognized this, as in the work of Girling[5], which points out how the level of blood pressure can greatly modify the effectiveness of the sympathetic activity.

Can the 'dynamic resistance' give us information, in any simple manner, as to what is happening to the calibre of the vessels ? Differentiating equation (2) to derive the 'dynamic resistance' R' :

$$\frac{1}{R'} = \frac{dF}{dP} = N\left[V.G + P.V.\frac{dG}{dP} + P.G.\frac{dV}{dP}\right] \qquad (4)$$

If there were only the first term in the brackets we could associate changes in resistance with changes in the geometrical factor of the viscosity factor or both, but in non-linear cases the second and third terms may completely dominate the whole expression. A striking example where the substitution of the slope for the conventional resistance would lead to a paradox is at pressures close to the 'critical closing pressure' in vascular beds under considerable vasomotor tone. In this case the flow–pressure curve is markedly concave towards the pressure axis, and the slope becomes very steep as the point of zero flow is approached. One would be forced to say that the 'resistance' (that is, the 'slope' or 'dynamic' resistance) had become very low, for a very small change in pressure produces a large change in flow. Yet at the point where this 'dynamic resistance' is decreasing to a low value, the vessels are actually closing down. Clearly, no useful concept of the connexion between this 'dynamic resistance' and the size of the lumen of the vessels is possible. By all means let us use the 'slope' of the flow-pressure curves in proper context, but we must not substitute this 'dynamic resistance' for the standard 'Ohmologous' resistance of standard hæmodynamics. If we do, we are likely to make confusion worse confounded.

Production of Mutants of Tobacco Mosaic Virus by Chemical Alteration of its Ribonucleic Acid *in vitro*

WHILE many agents are known to act as mutagens on the living cell, there have been no convincing reports that the genetic character of isolated particles, such as viruses or transforming principles, have been changed *in vitro*. Recent results with tobacco mosaic virus help to overcome this difficulty. The infective unit of the virus is its ribonucleic acid component, which can be isolated in active form[1]. It is made up of 6,000 nucleotides that probably form a single chain[2].

Recently, Schuster and Schramm[3] have used nitrous acid to convert adenine, guanine and cytosine into hypoxanthine, xanthine and uracil, respectively, while the ribonucleic acid strand remains intact. It was shown that the alteration of any one of about 3,000 nucleotides is lethal. Possibly, changes of other bases are mutagenic.

Table 1. MUTAGENIC EFFECT OF NITROUS ACID ON RIBONUCLEIC ACID. 2 vol. of 0·19 per cent ribonucleic acid extracted from tobacco mosaic virus *vulgare* by phenol (ref. 1) were mixed with 1 vol. 4 M sodium nitrite and 1 vol. 1 M acetate pH 4·8 at 22° C. After time t, the ribonucleic acid is diluted to 19 μgm./ml. with $M/15$ phosphate, and assayed. Control dilutions of untreated ribonucleic acid contain an equivalent amount of nitrite. Time τ (equation 1) is 18·5 min. Total infections are given as numbers of lesions (per leaf) on Xanthi, and as the sum of chlorotic and necrotic lesions on Java ; mutant infections as numbers of necrotic lesions per leaf on Java

t (min.)	t/τ	Total infections		Mutant infections	Mutant infections (per cent)
		Xanthi	Java	Java	Java
1	0·05	72·8	183	1·4	0·8

8	0·43	89·8	188	4·5	2·4
16	0·86	59·3	97	5·4	5·6
32	1·73	36·1	63	6·6	10·5
64	3·46	10·4	21	2·1	9·8
96	5·2	2·7	3·5	0·5	15·5
Untreated controls, μgm./ml. ribonucleic acid					
19		155	138	0·3	0·2
1·9		31·2	42	0·1	0·3
0·19		3·1	10	0	—
× 0·019		0·3	0·8	0	—

On the basis of this work we studied a simple symptom of mutation, the production of necrotic lesions on a tobacco variety (Java) on which the untreated strain produces chlorotic lesions only. Virus or isolated ribonucleic acid was treated with nitrous acid. After times t, samples were diluted to a constant concentration for assay on Xanthi and Java tobacco plants. The conditions and results are given in Table 1. The total concentration n of infective particles was measured by the number of lesions on Xanthi, and of chlorotic and necrotic lesions on Java tobacco, as compared with standard dilution curves. n decreases exponentially with t :

$$n = n_0 \exp(-t/\tau) \qquad (1)$$

where τ is the average time for one lethal conversion of a base per ribonucleic acid molecule.

The necrotic lesions on Java tobacco are due to mutated particles, and their number is expected to be nearly proportional to their concentration m. If the alteration of a single base is mutagenic, and if the average number of such mutations per ribonucleic acid molecule in the time τ is p, the concentration of such mutants is :

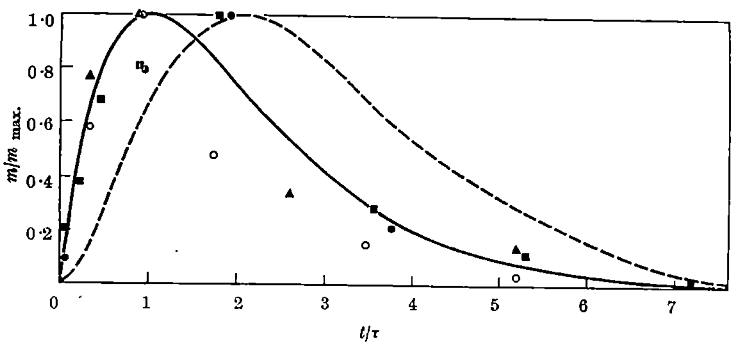

Fig. 1. Dependence of the concentration of mutants (number of necrotic lesions on Java tobacco, relative to maximum value) on the time of incubation with nitrous acid, related to τ. ———, Single-hit curve (equation 3); – – –, double-hit curve; ▲, tobacco mosaic virus *vulgare* (assayed at 0·7 μgm./ml.); ●, ribonucleic acid from tobacco mosaic virus *vulgare* (assayed at 39 μgm./ml.); ■, ribonucleic acid from tobacco mosaic virus *vulgare* (assayed at 19 μgm./ml.); ○, ribonucleic acid from light-green strain *B*11 (assayed at 9·5 μgm./ml.)

$$m = n_0 p \frac{t}{\tau} \exp(-t/\tau) = np\frac{t}{\tau} \qquad (2)$$

or in terms of the maximum value of m:

$$\frac{m}{m_{\text{max.}}} = e\,\frac{t}{\tau}\exp(-t/\tau) \qquad (3)$$

Fig. 1 represents measurements under different conditions with tobacco mosaic virus and with ribonucleic acid derived from two strains. For each case, τ was determined experimentally, using equation (1). The numbers of necrotic lesions on Java tobacco, divided by the maximum value reached in time t, were plotted against t/τ. The experimental results were in agreement with the theoretical relation (3).

The results lead to the following conclusions.

(1) Ribonucleic acid and tobacco mosaic virus treated with nitrous acid give rise to a much larger number of necrotic lesions on Java than untreated material assayed at the same concentration; it is twenty times the spontaneous level when total infectivity has dropped to only half the original value (Table 1). This appearance of mutants at low rates of inactivation excludes selection, and cannot be due to pre-existing mutants, or to mutants arising in the plant.

(2) The mutagenic effect on tobacco mosaic virus and on its isolated ribonucleic acid is equal when the fraction of bases altered in the ribonucleic acid, measured by t/τ, is the same. Also, tobacco mosaic virus treated with nitrous acid has the same proportion of mutants as ribonucleic acid isolated after the treatment. Thus, the mutants are produced by chemical reactions with ribonucleic acid rather than by aggregation phenomena, or by changes in the protein.

(3) The production of mutants is at first linear with t and follows a single-hit curve, irrespective of varying conditions (Fig. 1). Therefore, alterations of single nucleotides are mutagenic.

At $t = \tau$, where one out of about 3,000 nucleotides is altered[3], 6 per cent of the primary infections on Java plants infected with *vulgare* are found to be necrotic (Table 1). If the plating efficiency is assumed to remain unchanged upon mutation, the alteration of any one out of 180 of the total 6,000 nucleotides in the ribonucleic acid strand would be mutagenic, leading to necrotic lesions on Java; this assumption may be subject to later correction.

(4) A variety of other mutants is also produced by nitrous acid. In order to detect them, we isolated individual lesions produced by ribonucleic acid treated with nitrous acid on Xanthi tobacco ($t/\tau = 5 \cdot 2$, Table 1) and assayed them on Java and Samsun plants. Out of 60 lesions, 20 produced no infection, 33 led to a variety of altered symptoms and only 7 gave apparently unchanged symptoms on Samsun tobacco. The altered symptoms proved genetically stable in a transfer experiment. From a control dilution of untreated ribonucleic acid, 64 out of 65 lesions produced infection and no altered symptoms were detected.

We are led to conclude that the chemical alteration of individual bases of the ribonucleic acid molecule *in vitro* is mutagenic. A variety of different mutants may be produced in this way. It remains undecided which of the three types of chemical change caused by the nitrous acid (see above) are mutagenic, and how the chemically altered ribonucleic acid is related to its progeny. In the case of a conversion of cytosine into uracil, it is conceivable that the altered ribonucleic acid undergoes identical reproduction in the host cell.

We are much indebted to Prof. G. Melchers for generous support and advice, and to Prof. G. Schramm and Dr. H. Schuster for helpful discussions. A detailed account of this work is being published in the *Zeitschrift für Vererbungslehre*.

Correlated Failure of Synthetic Activities in a Wheat Chromosome

The process of chromosome condensation during meiotic prophase, with its uniformity and synchronization of all parts of the nucleus, provides evidence in support of the genotypic control of chromosome behaviour. So characteristic is this co-ordinated development that any exceptions to it have been considered as due to a basic differentiation of chromosome material into euchromatin and heterochromatin[1]. I have, however, shown recently[2] that the normal synchronized condensation of chromatin threads in the pollen mother cells of perennial ryegrass can be induced to break down by experimental means. This and the other induced changes which affect nucleolus organization have provided evidence pointing to a common control of metabolic activities in chromosomes. In the present experiment, the uniformity characterizing the behaviour of chromosomes in bread wheat has been observed to break down, though the techniques involved here are of a very different nature.

In the New Pusa wheat variety 797, meiosis is entirely regular except for the occurrence in some of the plants of one or rarely two small chromosome fragments in many of their pollen mother cells. Ahuja (personal communication, 1957), who analysed a large number of plants, found that the "fragments nearly always lie away from the nucleolus". Neither the pollen fertility nor the regular behaviour of chromosomes, however, is found to be affected because of the presence of fragments which obviously owe their origin to spontaneous chromosome breakage. During the course of some mutation-breeding experiments, a number of seeds of this variety were treated with an X-ray dose of 10,000 r. (50 kV.) after soaking in water for 24 hr. The X_2 progeny raised from one of these seeds consisted of plants having one or more fragments in their pollen mother cells, some of them also having a multiple association resulting from reciprocal translocations of chromosomes.

In a number of plants showing such breakage, either a single fragment or two were found to be closely associated with the nucleolus in a very large number of cells (Fig. 1). The consistency with which this association was observed naturally suggested that the nucleolar-organizing region of one of the nucleolar chromosomes might be forming part of the fragment. The suggestion is supported by the presence of a constriction in it and also of a heteromorphic bivalent close to the nucleolus which, however, is not always clearly seen. It is further supported by observations on the root-tip chromosomes of X_3 seedlings, some of which show the presence of only three chromosomes with secondary constrictions in their nuclei (Fig. 2), in contrast to the four invariably found in the control material.

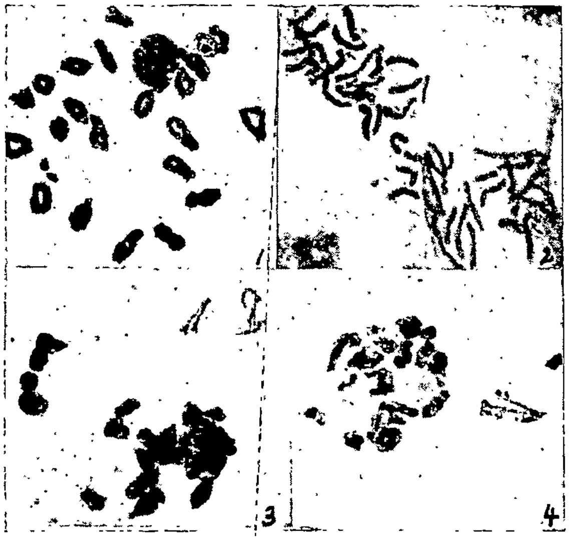

Fig. 1. 1, Pollen mother cell with two constricted fragments, one attached to the nucleolus. Of the 21 II, one close to nucleolus appears heteromorphic. 2, Root-tip cell showing the presence of only three chromosomes with secondary constrictions. 3, An affected pollen mother cell at diakinesis with one of its chromosomes uncondensed. 4, Another cell showing a fragment associated with the nucleolus and two univalents, one of which is retarded. 1,3,4, Carnoy-acetocarmine squashes (× 770, 816, 810); 2, Feulgen squash (× 630)

The organization of the nucleolus by the organizer-carrying fragment is scarcely of any great significance in itself; it was found, however, in a number of plants showing such organization, that either a single chromosome or a pair are retarded in their prophase condensation in a few of the pollen mother cells. This non-synchronized development results in the presence in the same nucleus of chromosomes which present a highly condensed appearance typical of metaphase, and one or two others which are relatively unspiralized, showing poor stainability both with carmine and the Feulgen stains (Figs. 3 and 4). The retardation affects only one of the 21 chromosome pairs and then only in few of the pollen mother cells.

It is not possible from the present observations alone to establish clearly the identity of the chromosome which shows retarded development. The earlier work on rye grass[2], however, strongly suggests that it must be the one which has its nucleolar-organizing region removed by breakage. In rye-grass, it has been shown that following high-temperature treatment, the nucleoli are organized adventitiously on each of the seven chromosomes. If, however, one or more of them fail to take part in nucleolar synthesis, they are invariably retarded in their prophase development. In the case of wheat, it is reasonable to suppose that a chromosome which has a particular site in it differentiated for the formation of nucleolus, may suffer in the synthesis of nucleolar material in the absence of this region; even though it is obvious from the work on rye-grass as well as from other studies[3,4] that an organizer is not always indispensable for nucleolar formation, its main function probably being to collect materials from all other chromosomes also rather than to synthesize them exclusively.

If it is accepted that the retarded chromosome in wheat is invariably the one which fails in its nucleolar synthesis in the absence of its organizing region, it follows that nucleolar formation and chromosome condensation are related phenomena. Since the prophase condensation of chromosomes is known to be conditioned by deoxyribonucleic acid—the Feulgen reaction of the affected chromosome is in agreement with this—the argument can be extended to suggest that the synthesis of deoxyribonucleic acid and nucleolar material in a chromosome are closely correlated.

A possible explanation of this relationship is suggested by the observations of Caspersson[5], Beermann[6] and others, which indicate that the nucleolar material represents the accumulated primary gene products. It is not unlikely that the factors which affect the capacity of the genic material to synthesize its primary products at telophase would also affect its own reproduction during later stages.

I am grateful to Dr. B. P. Pal and Dr. S. M. Sikka for their kind interest and encouragement; my thanks are also due to Dr. M. S. Swaminathan for a discussion of the results and to Mr. G. R. Rao for his competent technical assistance.

Transmission of Phenotypic Variability within a Pure Line

IN the course of a study of the genetic and environmental factors controlling heat resistance in peas (*Pisum sativum*), it was found that when the source of pollen was non-uniform with respect to the environment under which it was developed, the F_1 population exhibited a variance in growth which exceeded considerably that of either parent. Upon analysis of the results it was found that the excessive variance could be attributed entirely to the difference among the environments of the different pollen sources. This suggested that there may be a carry-over by the pollen of environmental influences on the pollen parent.

Two inbred lines of peas were used in these experiments, both lines having been inbred since the early 1930's. It is therefore most likely that these two lines, which have gone through an intensive inbreeding and selection programme extending for some 20–25 years, are for all practical purposes homozygous. All the experiments were performed in the Earhart Plant Research Laboratory. A description of this Laboratory and the experimental facilities available in it has been given by Went[1].

The seeds of both varieties were planted in either constant temperature – artificial light chambers, or in controlled fluctuating temperatures in greenhouses with natural light supplemented by artificial light to make a 16-hr. photoperiod. The temperature fluctuation of the greenhouse consists of a constant temperature during the day period and a constant but lower temperature during the night period.

Crosses were made between the two varieties used in these experiments and within each variety. The crosses were made in the following manner. The plants used as females were grown in a greenhouse with 16-hr. photoperiod and a controlled day temperature of 20° C. and a night temperature of 14° C. These plants were pollinated with pollen from plants growing in different constant temperatures. The F_1 progenies from these crosses were grown at 26° C., 16-hr. photoperiod, to test for heat resistance. It was during this phase of the experiments that differences in the growth characteristics among members of the F_1 population were observed. These differences are related to the temperatures in which the pollen donors had grown.

Table 1 summarizes the results of one experiment and shows the manner in which the crosses were made. A significant difference among pollen sources is shown by the significant differences in the growth behaviour of the three different groups.

Table 2 is a summary of the analysis variance of four separate experiments. In each experiment the contribution to the total variance caused by differences in pollen source, is significant.

Table 1. THE EFFECT OF GROWTH TEMPERATURE OF THE POLLEN-DONOR ON THE GROWTH CHARACTERISTICS OF THE F_1 PROGENY GROWN AT 26° C. ALL PLANTS GROWN ON A 16-HR. PHOTOPERIOD. FEMALE PARENTS GROWN AT 20° C. DURING LIGHT PERIOD, 14° C. DURING DARK PERIOD

These experiments, along with others[2] which have shown that differences can be produced in the growth characteristics of pea plants as a result of the effect of the environment on previous generations, are remarkably similar to those reported by Durrant[3] in flax.

Further studies of the relationship between the previous environment and the effect on the progeny are in progress and will be reported in due course. This work was supported by a grant from the National Science Foundation, Grant No. G1385.

Silicification of Branched Cells in the Leaves of *Nardus stricta* L.

ATTENTION has been directed[1] to the presence of certain peculiar branched rods of opaline silica in the leaves of *Nardus stricta* and in the soils on which this species grows. Although transverse sections of leaves of *N. stricta* figured by Grob[2] and Hegi[3] show what are apparently the minute hat-like opals which we have detected even in the very young leaves, we have found no reference depicting or describing the branched rods which we detect in surface preparations of older leaves after rendering them transparent, for example, by controlled treatment with chromic acid (Fig. 1). The branched cells which secrete these bodies, although not present in the seedling leaves, develop later on the well-marked ribs of the upper surface (Figs. 2 and 3), and their protruding portions can be identified with what have been described as asperities[4] or papillæ[2]. The protrusions tend to be longest near the crest of the rib, diminishing laterally to give every gradation from well-branched to unbranched long cells (Figs. 4 and 5).

This structure, with its end-to-end arrangement of long cells, is quite distinct from those involving the common types of trichome, and although we have examined many species of grasses we have seen it only in *N. stricta*. Stebbins[5] suggests that a distinctive genus such as *Nardus*, with its single species, may represent the last remains of some evolutionary line now almost extinct, or the culmination of a trend which has been successful in one specialized sphere. If it should be confirmed that no other grass besides *N. stricta* exhibits these branched cells and branched opaline bodies, it would give additional support to such theories.

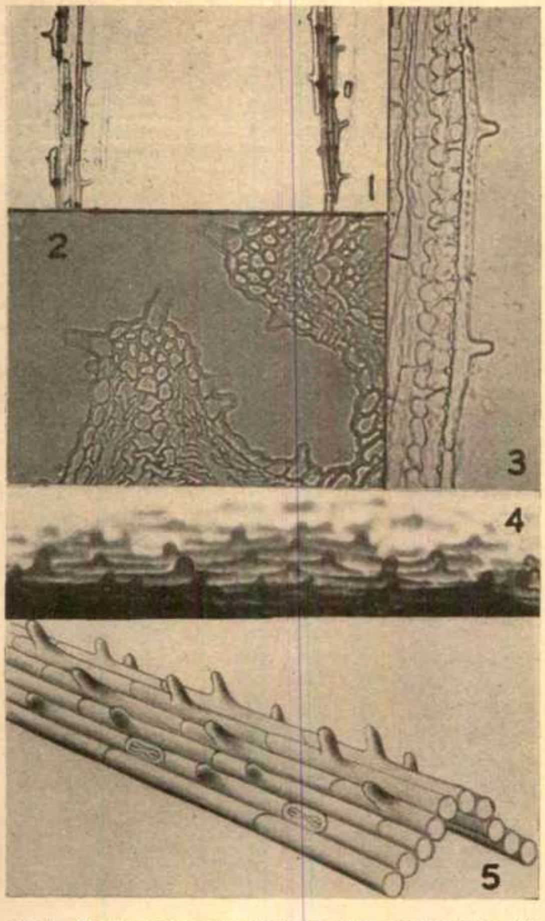

Fig. 1. *Nardus stricta*. Branched rods of opal in two ribs of the upper surface of the leaf (× 100). Fig. 2. Transverse section (× 270). Fig. 3. Longitudinal section (× 270). Fig. 4. Rows of branched cells in one rib, darkened by chromic acid treatment (× 220). Fig. 5. Diagrammatic representation of surface cells in one rib

The progressive silicification of *Nardus* leaves is being further investigated with material collected at intervals throughout the year. The special techniques used in this work have already been described[6].

Alary Polymorphism in the Gerroidea (Hemiptera Heteroptera)

THE Gerroidea exhibit a marked alary polymorphism which has promoted many investigations since that of Poisson[1], who classified the various forms and attempted to investigate the genetics of this polymorphism by breeding experiments. This lead was followed by Ekblom[2] and Guthrie[3] without reference to Mitis[4], who had suggested a possible link between life-cycles and polymorphism. These breeding experiments have given varied and confusing results, and one may only conclude that any form can give rise to any other and that, as Guthrie[3] decided, the problem is not one of simple genetics.

In a recent study of the biology of *Gerris* and *Velia* species, I have been able to extend the observations made by Mitis[4], illustrating a close relation between life-cycle, habitat and polymorphism[5]. Only bivoltine species were seen to be polymorphic, the univoltine species being predominantly monomorphic. Of the univoltine species, *Gerris najas* (Deg.) and the *Velia* species are most commonly apterous and usually inhabit running water, whereas the monomorphic univoltine species inhabiting ponds and pools (*G. costai* (H.-S.), *G. gibbifer* Schum.) are mostly macropterous. In these instances it seems that the needs of distribution have determined the form of the single generation. Poisson[1] showed that short-winged forms were more abundant in the summer, and I have found that they are restricted to the summer generation in most cases. *G. argentatus* Schum., *G. odontogaster* (Zett.) and *G. thoracicus* Schum. exhibit an alternation between a macropterous overwintering generation and a polymorphic summer generation, while *G. paladum* appears to have an entirely short-winged summer generation. Two further species (*G. lacustris* (Linn.) and *G. lateralis* Schum.) resemble *G. odontogaster* but have in addition a small proportion (less than 10 per cent) of short-winged forms in the over-wintering generation.

All these species spend the winter months on land as adults, flying to and from over-wintering sites in the autumn and spring respectively. Having established themselves on suitable habitats these insects then resorb their wing-muscles and breed, producing in most instances a mixed generation of long- and short-winged forms. The species that do this occupy small ponds, pools and ditches or limited areas of lake-fringes. Since short-winged forms contain the same number of eggs as long-winged forms, and they both grow at the same speed[5], the usual theories of the significance of short-wingedness are no longer adequate. Instead I wish to stress the inability of short-winged forms to fly—an obvious but neglected point of view. It has been noted that long-winged forms lose their powers of flight after over-wintering and before breeding, as in many insects. The following generation consists of approximately equal numbers of flightless forms, which maintain the breeding population on the pond on which the species has already bred successfully, and alate forms which are capable of migration if the pond becomes either over-populated or a poor habitat (due to surface pollution, drought, etc.). In this context it should be recalled that *G. paludum* has an entirely short-winged summer generation, but inhabits the open water of lakes and large ponds and is not therefore exposed to the same selective pressures as described above. The alternation of a long-winged and a polymorphic or short-winged generation reflects the alternation of habitats occupied by the insects.

Ford[6] described three ways by which a balanced polymorphism such as this could be maintained: switching by simple genic segregation (as in *Sitona*[7]), selective predation alternately favouring one form and then the other, where both forms are produced in each generation (as in *Adalia*[8]), or by the switching of a gene complex by environmental factors. Mather[9] regarded the last method as the simplest system which could produce the situation in which types "successively vanish and reappear in a population", as I have observed to occur in these insects.

This approach to an old problem will be described in greater detail elsewhere, but it would seem that the results of previous breeding experiments must be largely discounted on the grounds that the offspring produced from any one form varies from one generation to the next, and most authors combine the results of breeding experiments made throughout the season. As the polymorphic form resulting from each breeding is probably influenced by the environment, the laboratory conditions should be carefully controlled. We are now in a position to select a species with a distinct 'alternation of generations' and attempt to operate the switch mechanism by such controlled breeding.

Carbon Dioxide Fixation in Germinating Pine Pollen (*Pinus ponderosa*)

CARBON dioxide fixation by plant tissues other than those involved in photosynthesis has recently been reported for whole plant tissues and cellular particulates of roots[1,2]. This communication reports observations on the incorporation of carbon dioxide into the organic acid, amino-acid, and protein fractions of germinating pine pollen.

Pinus ponderosa pollen was germinated for 15 hr. at 29° C. in 0·01 *M* calcium–potassium phosphate buffer, *p*H 5·9, in the presence of the fungistat – bacteriostat mixture 'Mysteclin' (an antibiotic – antifungal mixture composed of tetracycline and mystatin; kindly supplied by the Medical Division, E. R. Squibb and Sons, New Brunswick, New Jersey). Radioactive potassium bicarbonate was added, and then the mixture was shaken for 1 hr. in a Warburg flask at 25° C. The reaction was stopped by acidification and the excess carbon dioxide removed by bubbling through inert carbon dioxide for 15 min. The mixture was then centrifuged and the supernatant removed from the pollen residue.

Table 1. PERCENTAGE OF CARBON-14 DIOXIDE INCORPORATED BY *Pinus ponderosa* POLLEN

Experiment	In supernatant		
	Total	Ether extract	Alcohol extract
1	24·6	11·2	2·1
2	34·1	13·1	3·4

Reaction mixture contained 200 mgm. pollen germinated 15 hr., 29° C.; 0·8 mgm. 'Mysteclin' in 0·002 *M* potassium phosphate buffer, *p*H 5·9. 0·5 μmoles potassium bicarbonate containing 125,000 counts/sec. was added after equilibration. The side-arm contained 0·5 ml. 2 *N* sulphuric acid added after 1 hr. incubation. Total volume, 2·5 ml.; temperature, 25° C.; incubation time, 1 hr.

Table 2. EFFECT OF PHOSPHOENOLPYRUVATE ON CARBON-14 DIOXIDE FIXATION BY GERMINATING POLLEN (*Pinus ponderosa*)

*p*H	Treatment	Percentage carbon-14 dioxide activity incorporated into	
		Supernatant	Residue
4·8	Heat inactivated	0·3	0·0
	Without phosphoenolpyruvate	9·0	0·6
	With phosphoenolpyruvate	10·7	0·5
7·4	Heat inactivated	0·3	0·0
	Without phosphoenolpyruvate	11·8	0·7
	With phosphoenolpyruvate	13·8	0·7

Reaction mixture the same as under Table 1 except 7 mgm. phosphoenolpyruvate was added where indicated; 90 μmoles phosphate buffer in each individual flask.

The total amount of radioactive carbon dioxide incorporated was determined by measuring the activity in aliquots of the supernatant and the residue. An ether extract and an alcohol extract of the reaction mixture were prepared. Activities in each of these fractions were ascertained by plating and counting in a windowless flow counter.

Table 1 indicates that most of the carbon-14 dioxide incorporated was in acid- or water-soluble components in the supernatant solution. After 1 hr. incubation, carbon-14 dioxide incorporated was higher in the organic acid fraction extractable in ether than in the alcohol-soluble components of the pollen supernatant.

Since many studies have indicated the presence of phosphoenolpyruvate carboxylase in plant tissues[3], the capacity of phosphoenolpyruvate to increase the incorporation of carbon dioxide by the pollen was investigated.

As Table 2 shows, carbon dioxide fixation increased when phosphoenolpyruvate was added to the incubating solution. About the same increase occurred whether the incubating medium was at the optimal *p*H of the phosphoenolpyruvate carboxylase or closer to the physiological *p*H. This agreement may be due to the high internal buffering capacity of the whole cell. The optimum *p*H for *P. ponderosa* pollen germination is 5·9, and germination is inhibited below *p*H 5·0 and above *p*H 7·0. This fact probably explains the total lower incorporation in the results shown in Table 2 as compared with those in Table 1. The stimulation due to phosphoenolpyruvate noted in particulate preparations[2] was much larger than that observed here. Since the inherent levels of phosphoenolpyruvate in pollen are quite high, perhaps alternate mechanisms of carbon dioxide fixation exist in germinating pollen or the treatment procedure used may not be optimal.

The pollen residues, which were insoluble in alcohol and ether, were hydrolysed overnight in 6 *N* hydrochloric acid at 117° C. Two-dimensional paper chromatograms were prepared of the alcohol extract of the hydrolysate using phenol/water and butanol/propionic acid/water as the solvents. The radioautographs showed activity in serine, aspartate, glutamate and malate. Radioautographs of the ether extract of the supernatant showed activity in malate, in what appeared to be citrate and in another organic acid.

The net synthesis of labelled amino-acids and possibly protein by germinating pollen, as evidenced by the hydrolysate studies, indicates that pollen on germinating into the female tissue not only absorbs water and activates inherent enzyme systems but probably can also synthesize the protein constitutive units of enzymes. Since pollen generally grows in a highly anaerobic environment, the capacity of pollen to incorporate carbon dioxide and synthesize amino-acids, proteins and possibly cell-wall materials may be an important growth mechanism in the plant reproductive cycle. The reduction and incorporation of carbon dioxide, coupled with the oxidation of carbohydrates present in the female gametophyte tissue, may in part be the mechanism by which rapid tube elongation can occur in pollen grains with only very limited carbon substrates.

This study was supported in part by grants from Resources For the Future, Inc., and the National Science Foundation.

Effect of the Cotton Plant in the Sudan Gezira on Certain Leaf-feeding Insect Pests

COTTON in the Sudan Gezira, where some 240,000 feddans (1 feddan = 1·034 acres) of *Gossypium barbadense* L. are grown by gravity irrigation from the Sennar Dam, is attacked, particularly during the first 3½ months of its growth, by three important leaf-feeding insects, namely, the jassid, *Empoasca libyca* de Berg.; whitefly, *Bemisia tabaci* Gen. and thrips, *Hercothrips fumipennis* Bag. and Cam.[1]. These insects may cause important loss in yield of seed cotton[2], but their intensity of attack varies from season to season[2,3]. If, however, application of control measures is delayed until damage is easily visible, yield benefit from such control may be seriously reduced[2]. An object of entomological research is prediction of outbreaks of economic significance.

One cause of the seasonal variations in numbers was elucidated recently by a study of the effect of nitrogenous fertilizer on these pests. In an experiment in which 1 N. or 2 N. (where 1 N. is equivalent to 45 rotls of nitrogen; 1 rotl = 0·99 lb.) per feddan as ammonium nitrate was applied to cotton at different dates during the first 3½ months after sowing, it was found that the estimated Kjeldahl nitrogen in the dry matter of the foliage of plants receiving fertilizer was greater than in those not receiving fertilizer. Nevertheless, there was a tendency in all investigated treatments for the concentration of leaf nitrogen to fall as the season progressed, while infestations of jassids and whitefly increased with time. When, in an analysis of covariance, these latter effects were eliminated, a highly significant regression of jassid and whitefly densities on concentration of leaf nitrogen could be demonstrated. This finding is reminiscent of the work of Allen and Selmon[4] on *Phaedon cocleariae* F., and Le Roux[5] on *Tetranychus bimaculatus* Harvey, to quote two recent examples, and it is believed to be due to an increase in birth-rate with increased concentration of leaf nitrogen.

Table 1. MEAN NITROGEN CONCENTRATION IN COTTON LEAVES (PER CENT OF DRY WEIGHT) IN FIVE SAMPLES TAKEN BETWEEN EARLY SEPTEMBER AND LATE OCTOBER DURING FOURTEEN SEASONS

Locality	0 N. plots	3 N. plots	Mean
Hag Abdulla (south)	3·51	3·70	3·60
Gezira Research Farm (centre)	3·70	3·84	3·77
Turabi (north)	3·87	3·98	3·93
Mean	3·69	3·84	3·76

	Sites	Nitrogen
S.E.	±0·049	±0·059
Least sig. diff.		
($P = 0·05$)	0·14	0·17
($P = 0·01$)	0·18	0·22

Examination of results obtained by the Research Division on concentration of leaf nitrogen at three Gezira sites over fourteen seasons gave the means shown in Table 1.

The concentration of leaf nitrogen was affected by locality and fertilizer treatment. The effect on the two main Gezira cotton varieties, namely, *X*1730*A*, grown in the south, and Domain Sakel, grown in the north, was insignificant. There were also highly significant seasonal differences. Because of the established effect on Gezira cotton yields[6] of rains falling between July 1 and August 15 (pre-sowing rains) the covariance of concentration of leaf nitrogen on these rains was examined during the six seasons when all the cotton had been sprayed with DDT. The correlation coefficient of concentration of leaf nitrogen on pre-sowing rains was $-0·5842$ which, for 22 degrees of freedom, is highly significant. There was evidence, however, that the effect was not direct, and seasonal variation in concentration of leaf nitrogen was caused by some uninvestigated factor itself correlated with rainfall.

The regression of the mean September and October concentration of nitrogen in the leaf material of the cotton plant on pre-sowing rains could be expressed by the equation:

$$X_2 = 4·07 - 0·0031X_1$$

where X_2 is the mean concentration of leaf nitrogen during September and October (as percentage of dry matter), and X_1 is the rainfall in mm. during July 1–August 15. The standard error of the regression coefficient is $\pm$ 0·0009).

The seasonal incidence of pests feeding on the leaves was recorded during four seasons at one site (Gezira Research Farm), and was found to be correlated with pre-sowing rains and the concentration of leaf nitrogen. The regression equation for rate of jassid increase is:

$$a = 18·03 - 0·071X_1\ (\pm 0·010)$$
$$a = 10·96X_2\ (\pm\ 0·69) - 35$$

where a is the mean rate of increase in jassid nymphs per 100 leaves per day

(other symbols as before, with standard errors of regression coefficients in brackets). This describes the rate of increase during September and October before spraying as well as that during October and November after DDT spraying.

The mean infestations during October and November, namely, after spraying, and at a time when the pests are considered to exert most effect on crop yields, were:

$$\text{Jassids}: \; Y_1 = 156{\cdot}4X_2 - 478 \; (\pm 20{\cdot}4)$$
$$\text{Whitefly}: \; Y_2 = 9{\cdot}71X_2 - 0{\cdot}27 \; (\pm 0{\cdot}17)$$
$$\text{Thrips}: \; Y_3 = 4{\cdot}16X_2 - 0{\cdot}89 \; (\pm 3{\cdot}17)$$

where Y_1 is the mean number of nymphs of *E. libyca* per 100 leaves, Y_2 is the mean number of adults of *B. tabaci* (logarithm), and Y_3 is the percentage of leaves infested with larvæ of *Hercothrips* sp. (arc sin/percentage) (other symbols as before).

The regression coefficients for whitefly and jassid infestations were highly significant: that for thrips was not significant.

E. libyca is preyed upon by the Mymarid egg parasites *Anagrus* sp. and *Paranagrus* sp. while the *Aphelinid* parasites *Eretmocerus* sp. and *Prosaptella* sp. cause heavy mortality of the later instars of *B. tabaci*. All these parasites appear to be more numerous in seasons of good than of poor pre-sowing rains, but statistical evidence is deficient.

The results, although incomplete, raise the interesting possibility that the cotton plant in the Sudan Gezira may, by the seasonal changes in composition of its foliage expressed by percentage of Kjeldahl nitrogen, influence the rate of increase of some of its leaf-feeding insects in such way as to enable them to 'break away' from biological controlling agents. According to F. Crowther[7] the concentration of nitrogen in cotton leaves is determined by: (1) the concentration of nitrogen in the soil and (2) the rate of development of the plant. Jewitt[8] showed that the nitrate-nitrogen in Gezira soils was negatively correlated with pre-sowing rains. The results so far available do not indicate that rains control leaf nitrogen directly, but determine it through other correlated factors influencing the early rate of development of the cotton plant.

It is hoped that this knowledge, considered in relation to some other aspects of the ecology of the pests concerned, will enable prediction to be made of pest outbreaks in the Sudan Gezira before the crop is sown. A full account of this approach in relation to the cotton jassid will be published elsewhere.

I am grateful to Sayed Ahmed Kordofani, of the Research Division, for access to his records of the growth and composition of the cotton plant in the Sudan Gezira, and to the Chief of Agricultural Research, Ministry of Agriculture, Sudan Republic, for permission to publish this work.

Bat Erosion as a Factor in Cave Formation

I have read with much interest the communication by W. A. King-Webster and J. S. Kenny[1] in which it is suggested that roosting bats can play a considerable part in cave excavation where the rock is soft. In particular, reference is made to the existence, in the roof of a limestone cave in Mt. Tamana (Trinidad), of bell-shaped cavities ranging in depth from 3 ft. to 6 ft., and in diameter at the mouth from 1½ ft. to 2½ ft., and which are used by sleeping bats. The suggestion is made that the habit of the bats of alighting at the lower edge of the bell and then jostling upwards into a central position, by continuation over innumerable years, has led to the excavation of these cavities, with maximum removal of rock at the mouth of the bell.

Ceiling cavities of the type described are, however, a commonplace feature in many limestone caverns and indeed in portions of those caverns that have never been known to have been used by bats. This applies particularly to tunnels so far in linear distance from the cave entrance or in depth below it that they are beyond the normal zone of penetration of the bats. Such ceiling pockets, and also similar indentations in cave walls, have been described by Bretz in his classic paper[2], in which he elaborates on the theories, originally proposed by Davis[3], concerning the phreatic origin of certain types of cave tunnels and systems. Bretz specifically quotes such wall and ceiling pockets as examples of cave features of phreatic origin, pointing out that it is difficult to visualize their formation by any solution mechanism under conditions whereby there was an air space above the water surface. He therefore considers that such ceiling pockets were formed below the lowest normal water-table level (such as might occur at times of drought) and he directs attention to the fact that if the 'eating-out' process is continued long enough, adjacent pockets merge into one another, thus producing one of the effects described by King-Webster and Kenny.

During the course of the studies made by my wife and myself on the habits of certain cave-dwelling bats[4], in particular, the greater horseshoe bat (*Rhinolophus ferrumequinum*), we have often noticed ceiling pockets, of the type described above, in the natural caverns that exist in scattered outcrops of Devonian limestone, in the neighbourhood of Buckfastleigh in Devon. Some of these pockets are commonly used during the winter months by the greater horseshoe bats, probably because such dome-shaped cavities provide areas of roof that are free from draughts. It is, however, important to note that these caves were only revealed as a result of quarrying operations during the past century, and they were thus not occupied by bats until they were opened to the outside world, barely a hundred years ago. Although we have evidence in Devon that the claws of a greater horseshoe bat can mark the roof of a cave, at least to the extent of scratching off powdery surface deposits from the limestone, it would be surprising indeed if the colonies of bats could have excavated roof pockets to a depth of several feet in such a limited time. I therefore feel that although the 'bat erosion' effect postulated by King-Webster and Kenny may well occur with certain types of limestone, it represents at best only a secondary, and probably minor, contribution to the shape and size of the ceiling pockets described.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 24

Royal Geographical Society (at 1 Kensington Gore, London, W.7), at 5 p.m.—Lieutenant C. J. Wynne-Edwards, R.N.: "Hydro- aphic Survey in the Falkland Islands Antarctic Dependencies".

British Society for the History of Science (in the Council om of the Science Museum, Exhibition Road, South Kensington, ndon, S.W.7), at 5.30 p.m.—Dr. G. J. Whitrow: "The Evolution Our Numerals and System of Numeration".

Institution of Electrical Engineers, Radio and Telecom- nication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.— . J. S. Seeley and Dr. J. Brown: "The Use of Dispersive Dielectrics a Beam-Scanning Prism"; Dr. J. S. Seeley: "The Quarter-Wave tching of Dispersive Materials"; Mr. A. Carne and Dr. J. Brown: heory of Reflections from the Rodded-Type Artificial Dielectric".

University of London (in the Anatomy Theatre, University llege, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. C. A. gers: "Packing and Covering".* (Inaugural Lecture.)*

Royal Aeronautical Society (at the Institution of Civil Eng- ers, Great George Street, London, S.W.1), at 6 p.m.—Mr. J. E. teman: "Inertia Guidance".

Tuesday, November 25

Institution of Chemical Engineers (at the Geological Society· rlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. H. E. se: "A Suggested Equation Relating to the Mixing of Powders d its Application to the Study of the Performance of Certain Types Machine".

University of London (at the London School of Hygiene and opical Medicine, Keppel Street, Gower Street, London, W.C.1), 5.30 p.m.—Dr. E. H. Mercer: "Electron Microscopy and the ructure of the Living Cell".* (Eighth of eleven lectures on "The ientific Basis of Medicine" organized by the British Postgraduate edical Federation. Further lectures on November 27 and December and 4.)

Society of Instrument Technology, Data Processing Section t Manson House, Portland Place, London, W.1), at 6 p.m.—Mr. . C. M. Barnes: "Digital Data-Recording for Nuclear Experiments".

Society for Analytical Chemistry, Physical Methods Group t the Chemical Society, Burlington House, Piccadilly, London, .1), at 6.30 p.m.—Fourteenth Annual General Meeting, followed meeting on "Modern Methods of Purification".

Wednesday, November 26

University of London (at the Postgraduate Medical School of ondon, Ducane Road, London, W.12), at 2 p.m.—Dr. H. M. Sinclair: Essential Fatty Acids".*

Geological Society of London (at Burlington House, Piccadilly, ondon, W.1), at 5 p.m.—Mr. Graham F. Elliott: "Fossil Calcareous lgal Floras of the Middle East"; Miss Leonora A. Stevens: "The terglacial of the Nar Valley, Norfolk" (paper communicated by r. R. G. West).

Royal Geographical Society (at 1 Kensington Gore, London, .W.7), at 5 p.m.—Prof. Max Mallowan: "Excavations at Nimrud, 958".

Institute of Marine Engineers (at the Memorial Building, 3 Mark Lane, London, E.C.3), at 5.30 p.m.—Sir John Cockcroft, .M., F.R.S.: "Recent Advances in Nuclear Engineering" (Sir harles Parsons Memorial Lecture).

Institution of Electrical Engineers, Supply Section (at avoy Place, London, W.C.2), at 5.30 p.m.—Dr. L. L. Alston and rof. F. M. Bruce: "Investigations of Power-Follow Current Phe- omena using a Synthetic Power Source"; Dr. L. L. Alston: "The mpulse Initiation of Arc Discharges".

British Institution of Radio Engineers (at the London School f Hygiene and Tropical Medicine, Keppel Street, Gower Street, ondon, W.C.1), at 6 p.m.—Annual General Meeting. 7.15 p.m.— rof. E. E. Zepler: Presidential Address.

Society of Chemical Industry, Food Group (at 14 Belgrave quare, London, S.W.1), at 6.15 p.m.—Scientific Papers.

British Psychological Society, Medical Section (at the Royal ociety of Medicine, 1 Wimpole Street, London, W.1), at 8.30 p.m.— r. John Bowlby: "Studies of Parent–Infant Interaction in Man nd Animals—some Notes on Projects in Progress".

Thursday, November 27

Institute of Physics, Electron Microscopy Group (at the Royal ociety of Arts, John Adam Street, Adelphi, London, W.C.2), at 0 a.m.—Meeting on "Electron Staining".

University of London (at the London School of Hygiene and ropical Medicine, Keppel Street, Gower Street, London, W.C.1), at .30 p.m.—Mr. Michael Abercrombie: "Cell Surface and the Control f Growth".* (Ninth of eleven lectures on "The Scientific Basis of ledicine" organized by the British Postgraduate Medical Federation. urther lectures on December 2 and 4).

Friday, November 28

Institute of Physics, Electron Microscopy Group and X-Ray nalysis Group (at the Institution of Civil Engineers, Great George treet, London, S.W.1), at 10 a.m.—Joint Conference on "Precipita- ion in Alloys".

Institute of Rural Life at Home and Overseas (at Friends International Centre, 32 Tavistock Square, London, W.C.1), at 1.15 p.m.—Mr. George Bredin: "The Impact of the Gezira Cotton-Growing Scheme on the Rural Population of the Blue Nile".*

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Turbidity Currents: High Speed Underwater Flow of Sediment Suspensions". Chairman: Dr. G. E. R. Deacon, F.R.S. Speakers will include Dr. A. S. Laughton, Dr. R. Stoneley and Dr. T. H. Ellison.

Physical Society (in the Large Lecture Theatre, Chemistry Department, Imperial College, Imperial Institute Road, London, S.W.7), at 5 p.m.—Prof. Niels Bohr, F.R.S.: "General Implications of the Atomic Nucleus" (9th (1958) Rutherford Lecture).*

Royal Anthropological Institute of Great Britain and Ireland (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Sir Wilfrid Le Gros Clark, F.R.S.: "Bones of Contention" (Huxley Memorial Lecture).

Institution of Electrical Engineers, Medical Electronics Discussion Group (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion Meeting on "Problems Encountered in the Field of Neurophysiology".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. Z. Young, F.R.S.: "Squids, Cuttlefishes and Octopuses".

Friday, November 28—Thursday, December 4

Electronic Computer Exhibition (at Olympia, London, W.14).*

Monday, December 1—Wednesday, December 3

Business Computer Symposium.

Saturday, November 29

Institute of Physics, X-Ray Analysis Group (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 9.30 a.m. —Scientific Papers.

Botanical Society of the British Isles (in the Lecture Room of the Royal Horticultural Society, Vincent Square, London, S.W.1), at 12 noon—Exhibition Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer, Grade B (with a degree in electrical engineering or physics and preferably a special knowledge or industrial experience of some branch of the subject), in Telecommunications and Electronics—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (November 28).

Assistant Lecturer (with an honours degree in physics and preferably able to teach the subject to a high standard) in Physics—The Principal, Wigan and District Mining and Technical College, Wigan (December 1).

Lecturer or Assistant Lecturer (with a good honours degree and teaching experience) in Biology at the Royal Technical College of East Africa—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (December 5).

Lecturer (with special qualifications in botany or agricultural botany) in Botany—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (December 5).

Lecturer or Research Assistant in Bacteriology and Virology —The Registrar, The University, Sheffield (December 6).

Research Assistant (preferably with a Ph.D. degree and suitable experience in biochemistry and microbiology) in the Department of Bacteriology, to assist in a programme of work on the immunochemistry of *Bordetella pertussis*—The Registrar, The University, Manchester 13 (December 6).

Senior Lecturer and a Lecturer in Mathematics at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, December 12).

Lecturer (graduate in metallurgy or chemistry with special qualifications in the theory and principles of extraction metallurgy) in Metallurgy—The Registrar, The University, Manchester 13 (December 13).

Senior Lecturer/Lecturer in Chemistry at the University of New South Wales, Sydney, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (Australia, December 13).

Reader in Aeronautics at Imperial College, London, S.W.7—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 15).

Senior Lecturer (registered pharmaceutical chemist) in Pharmacy at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 15).

Chair of Civil Engineering, Senior Lecturer or Lecturer in Mechanical Engineering, Lecturer in Engineering Mathematics, Lecturer in Civil Engineering, and a Lecturer in Electrical Engineering at the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 29).

Chair of Botany—The Registrar, The University, Hull (December 31).

Research Fellow in the Physiology Department, Faculty of Rural Science, University of New England, Australia, to undertake research associated with a study of the comparative physiology of mammalian erythrocytes with particular reference to the physiological significance of individuality in the ruminant erythrocyte—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 31).

LECTURERS or ASSISTANT LECTURERS IN PHYSIOLOGY at the University of Malaya—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

LECTURER or ASSISTANT LECTURER (preferably with qualifications in mathematical analysis and/or statistics) **IN MATHEMATICS** at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 10).

LECTURER IN PURE MATHEMATICS—The Secretary, Queen's University, Belfast (January 15).

BROTHERTON CHAIR OF CHEMICAL ENGINEERING in the Houldsworth School of Applied Science—The Registrar, The University, Leeds 2 (January 31).

ENTOMOLOGIST (with a good honours degree in zoology and an interest in, and aptitude for, taxonomic work, and preferably experience in the Diptera particularly the Calyptrata) at the Commonwealth Institute of Entomology, London—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (January 31).

BIOCHEMIST (with a Ph.D. degree or equivalent research experience), for work on the metabolism of cell and organ cultures—The Secretary, Strangeways Research Laboratory, Wort's Causeway, Cambridge.

EXPERIMENTAL OFFICER (at least 26 years of age, preferably with a pass degree, or at least H.N.C. (engineering or applied physics) or equivalent), to carry out experiments designed to investigate the mechanical strength of complex assemblies, to instrument parts for experiments and to analyse experimental results—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. A.1895/34.

PHYSICAL CHEMIST, PHYSICIST or METALLURGIST, for research on anodic oxide films—Dr. G. M. Shrum, Director, British Columbia Research Council, University of British Columbia, Vancouver 8, B.C., Canada.

READER IN NUCLEAR ENGINEERING at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1.

RESEARCH ASSISTANT (preferably with a Ph.D. degree in chemistry or biochemistry, for work on the biochemical analysis of *Haemophilus pertussis* antigens—The Secretary, The Lister Institute of Preventive Medicine, Elstree, Hertfordshire.

RESEARCH ASSISTANT, to help with quantum mechanical calculations on tetrahedral and other nearly spherical molecules, using an electronic computer—Dr. R. A. Buckingham, University of London Computer Unit, 44 Gordon Square, London, W.C.1.

RESEARCH FELLOW (with experience in acoustic measuring techniques) **IN PHYSICS**, for work on materials for use in acoustic assemblies—The Registrar, The University, Leicester.

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (honours graduate with a first- or good second-class honours degree), to undertake research on ceramic fuels for reactors, including the determination of physical and chemical properties over a wide range of temperatures, phase equilibria and investigation of fabrication techniques—The Group Recruitment Officer (1248/34), U.K.A.E.A., Atomic Energy Research Establishment, Harwell, Berks.

SENIOR RESEARCH OFFICER (PLANT PATHOLOGY) (with a good honours degree in botany (plant pathology) and suitable professional and administrative experience), to take charge of the Plant Pathology Division, Department of Agriculture, Kenya, and to guide and direct work of other pathologists in the Division—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/7/015.

SENIOR TECHNICIAN (capable of supervising setting-out of laboratories for physiological, biochemical and histological classes, and a knowledge of workshop techniques) **IN THE PHYSIOLOGY DEPARTMENT**—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

Alary Polymorphism in the Gerroidea (Hemiptera Heteroptera)

The Gerroidea exhibit a marked alary polymorphism which has promoted many investigations since that of Poisson[1], who classified the various forms and attempted to investigate the genetics of this polymorphism by breeding experiments. This lead was followed by Ekblom[2] and Guthrie[3] without reference to Mitis[4], who had suggested a possible link between life-cycles and polymorphism. These breeding experiments have given varied and confusing results, and one may only conclude that any form can give rise to any other and that, as Guthrie[3] decided, the problem is not one of simple genetics.

In a recent study of the biology of *Gerris* and *Velia* species, I have been able to extend the observations made by Mitis[4], illustrating a close relation between life-cycle, habitat and polymorphism[5]. Only bivoltine species were seen to be polymorphic, the univoltine species being predominantly monomorphic. Of the univoltine species, *Gerris najas* (Deg.) and the *Velia* species are most commonly apterous and usually inhabit running water, whereas the monomorphic univoltine species inhabiting ponds and pools (*G. costai* (H.-S.), *G. gibbifer* Schum.) are mostly macropterous. In these instances it seems that the needs of distribution have determined the form of the single generation. Poisson[1] showed that short-winged forms were more abundant in the summer, and I have found that they are restricted to the summer generation in most cases. *G. argentatus* Schum., *G. odontogaster* (Zett.) and *G. thoracicus* Schum. exhibit an alternation between a macropterous overwintering generation and a polymorphic summer generation, while *G. paladum* appears to have an entirely short-winged summer generation. Two further species (*G. lacustris* (Linn.) and *G. lateralis* Schum.) resemble *G. odontogaster* but have in addition a small proportion (less than 10 per cent) of short-winged forms in the over-wintering generation.

All these species spend the winter months on land as adults, flying to and from over-wintering sites in the autumn and spring respectively. Having established themselves on suitable habitats these insects then resorb their wing-muscles and breed, producing in most instances a mixed generation of long- and short-winged forms. The species that do this occupy small ponds, pools and ditches or limited areas of lake-fringes. Since short-winged forms contain the same number of eggs as long-winged forms, and they both grow at the same speed[5], the usual theories of the significance of short-wingedness are no longer adequate. Instead I wish to stress the inability of short-winged forms to fly—an obvious but neglected point of view. It has been noted that long-winged forms lose their powers of flight after over-wintering and before breeding, as in many insects. The following generation consists of approximately equal numbers of flightless forms, which maintain the breeding population on the pond on which the species has already bred successfully, and alate forms which are capable of migration if the pond becomes either over-populated or a poor habitat (due to surface pollution, drought, etc.). In this context it should be recalled that *G. paludum* has an entirely short-winged summer generation, but inhabits the open water of lakes and large ponds and is not therefore exposed to the same selective pressures as described above. The alternation of a long-winged and a polymorphic or short-winged generation reflects the alternation of habitats occupied by the insects.

Ford[6] described three ways by which a balanced polymorphism such as this could be maintained: switching by simple genic segregation (as in *Sitona*[7]), selective predation alternately favouring one form and then the other, where both forms are produced in each generation (as in *Adalia*[8]), or by the switching of a gene complex by environmental factors. Mather[9] regarded the last method as the simplest system which could produce the situation in which types "successively vanish and reappear in a population", as I have observed to occur in these insects.

This approach to an old problem will be described in greater detail elsewhere, but it would seem that the results of previous breeding experiments must be largely discounted on the grounds that the offspring produced from any one form varies from one generation to the next, and most authors combine the results of breeding experiments made throughout the season. As the polymorphic form resulting from each breeding is probably influenced by the environment, the laboratory conditions should be carefully controlled. We are now in a position to select a species with a distinct 'alternation of generations' and attempt to operate the switch mechanism by such controlled breeding.

Carbon Dioxide Fixation in Germinating Pine Pollen (*Pinus ponderosa*)

CARBON dioxide fixation by plant tissues other than those involved in photosynthesis has recently been reported for whole plant tissues and cellular particulates of roots[1,2]. This communication reports observations on the incorporation of carbon dioxide into the organic acid, amino-acid, and protein fractions of germinating pine pollen.

Pinus ponderosa pollen was germinated for 15 hr. at 29° C. in 0·01 *M* calcium–potassium phosphate buffer, *p*H 5·9, in the presence of the fungistat–bacteriostat mixture 'Mysteclin' (an antibiotic–antifungal mixture composed of tetracycline and mystatin; kindly supplied by the Medical Division, E. R. Squibb and Sons, New Brunswick, New Jersey). Radioactive potassium bicarbonate was added, and then the mixture was shaken for 1 hr. in a Warburg flask at 25° C. The reaction was stopped by acidification and the excess carbon dioxide removed by bubbling through inert carbon dioxide for 15 min. The mixture was then centrifuged and the supernatant removed from the pollen residue.

Table 1. PERCENTAGE OF CARBON-14 DIOXIDE INCORPORATED BY *Pinus ponderosa* POLLEN

Experiment	In supernatant		
	Total	Ether extract	Alcohol extract
1	24·6	11·2	2·1
2	34·1	13·1	3·4

Reaction mixture contained 200 mgm. pollen germinated 15 hr., 29° C.; 0·8 mgm. 'Mysteclin' in 0·002 *M* potassium phosphate buffer, *p*H 5·9. 0·5 μmoles potassium bicarbonate containing 125,000 counts/sec. was added after equilibration. The side-arm contained 0·5 ml. 2 *N* sulphuric acid added after 1 hr. incubation. Total volume, 2·5 ml.; temperature, 25° C.; incubation time, 1 hr.

Table 2. EFFECT OF PHOSPHOENOLPYRUVATE ON CARBON-14 DIOXID FIXATION BY GERMINATING POLLEN (*Pinus ponderosa*)

*p*H	Treatment	Percentage carbon-14 dioxide activity incorporated into	
		Supernatant	Residue
4·8	Heat inactivated	0·3	0·0
	Without phosphoenolpyruvate	9·0	0·6
	With phosphoenolpyruvate	10·7	0·5
7·4	Heat inactivated	0·3	0·0
	Without phosphoenolpyruvate	11·8	0·7
	With phosphoenolpyruvate	13·8	0·7

Reaction mixture the same as under Table 1 except 7 mgm. phosphoenolpyruvate was added where indicated; 90 μmoles phosphat buffer in each individual flask.

The total amount of radioactive carbon dioxide incorporated was determined by measuring the activity in aliquots of the supernatant and the residue. An ether extract and an alcohol extract of the reaction mixture were prepared. Activities in each of these fractions were ascertained by plating and counting in a windowless flow counter.

Table 1 indicates that most of the carbon-14 dioxide incorporated was in acid- or water-soluble components in the supernatant solution. After 1 hr. incubation, carbon-14 dioxide incorporated was higher in the organic acid fraction extractable in ether than in the alcohol-soluble components of the pollen supernatant.

Since many studies have indicated the presence of phosphoenolpyruvate carboxylase in plant tissues[3], the capacity of phosphoenolpyruvate to increase the incorporation of carbon dioxide by the pollen was investigated.

As Table 2 shows, carbon dioxide fixation increased when phosphoenolpyruvate was added to the incubating solution. About the same increase occurred whether the incubating medium was at the optimal *p*H of the phosphoenolpyruvate carboxylase or closer to the physiological *p*H. This agreement may be due to the high internal buffering capacity of the whole cell. The optimum *p*H for *P. ponderosa* pollen germination is 5·9, and germination is inhibited below *p*H 5·0 and above *p*H 7·0. This fact probably explains the total lower incorporation in the results shown in Table 2 as compared with those in Table 1. The stimulation due to phosphoenolpyruvate noted in particulate preparations[2] was much larger than that observed here. Since the inherent levels of phosphoenolpyruvate in pollen are quite high, perhaps alternate mechanisms of carbon dioxide fixation exist in germinating pollen or the treatment procedure used may not be optimal.

The pollen residues, which were insoluble in alcohol and ether, were hydrolysed overnight in 6 *N* hydrochloric acid at 117° C. Two-dimensional paper chromatograms were prepared of the alcohol extract of the hydrolysate using phenol/water and butanol/propionic acid/water as the solvents. The radioautographs showed activity in serine, aspartate, glutamate and malate. Radioautographs of the ether extract of the supernatant showed activity in malate, in what appeared to be citrate and in another organic acid.

The net synthesis of labelled amino-acids and possibly protein by germinating pollen, as evidenced by the hydrolysate studies, indicates that pollen on germinating into the female tissue not only absorbs water and activates inherent enzyme systems but probably can also synthesize the protein constitutive units of enzymes. Since pollen generally grows in a highly anaerobic environment, the capacity of pollen o incorporate carbon dioxide and synthesize amino-cids, proteins and possibly cell-wall materials may e an important growth mechanism in the plant eproductive cycle. The reduction and incorporation f carbon dioxide, coupled with the oxidation of arbohydrates present in the female gametophyte issue, may in part be the mechanism by which rapid ube elongation can occur in pollen grains with only ery limited carbon substrates.

This study was supported in part by grants from Resources For the Future, Inc., and the National Science Foundation.

Effect of the Cotton Plant in the Sudan Gezira on Certain Leaf-feeding Insect Pests

COTTON in the Sudan Gezira, where some 240,000 feddans (1 feddan = 1·034 acres) of *Gossypium barbadense* L. are grown by gravity irrigation from the Sennar Dam, is attacked, particularly during the first 3½ months of its growth, by three important leaf-feeding insects, namely, the jassid, *Empoasca libyca* de Berg.; whitefly, *Bemisia tabaci* Gen. and thrips, *Hercothrips fumipennis* Bag. and Cam.[1]. These insects may cause important loss in yield of seed cotton[2], but their intensity of attack varies from season to season[2,3]. If, however, application of control measures is delayed until damage is easily visible, yield benefit from such control may be seriously reduced[2]. An object of entomological research is prediction of outbreaks of economic significance.

One cause of the seasonal variations in numbers was elucidated recently by a study of the effect of nitrogenous fertilizer on these pests. In an experiment in which 1 N. or 2 N. (where 1 N. is equivalent to 45 rotls of nitrogen; 1 rotl = 0·99 lb.) per feddan as ammonium nitrate was applied to cotton at different dates during the first 3½ months after sowing, it was found that the estimated Kjeldahl nitrogen in the dry matter of the foliage of plants receiving fertilizer was greater than in those not receiving fertilizer. Nevertheless, there was a tendency in all investigated treatments for the concentration of leaf nitrogen to fall as the season progressed, while infestations of jassids and whitefly increased with time. When, in an analysis of covariance, these latter effects were eliminated, a highly significant regression of jassid and whitefly densities on concentration of leaf nitrogen could be demonstrated. This finding is reminiscent of the work of Allen and Selmon[4] on *Phaedon coclearíae* F., and Le Roux[5] on *Tetranychus bimaculatus* Harvey, to quote two recent examples, and it is believed to be due to an increase in birth-rate with increased concentration of leaf nitrogen.

Table 1. MEAN NITROGEN CONCENTRATION IN COTTON LEAVES (PER CENT OF DRY WEIGHT) IN FIVE SAMPLES TAKEN BETWEEN EARLY SEPTEMBER AND LATE OCTOBER DURING FOURTEEN SEASONS

Locality	0 N. plots	3 N. plots	Mean
Hag Abdulla (south)	3·51	3·70	3·60
Gezira Research Farm (centre)	3·70	3·84	3·77
Turabi (north)	3·87	3·98	3·93
Mean	3·69	3·84	3·76

	Sites	Nitrogen
S.E.	+0·049	±0·059
Least sig. diff.		
($P = 0·05$)	0·14	0·17
($P = 0·01$)	0·18	0·22

Examination of results obtained by the Research Division on concentration of leaf nitrogen at three Gezira sites over fourteen seasons gave the means shown in Table 1.

The concentration of leaf nitrogen was affected by locality and fertilizer treatment. The effect on the two main Gezira cotton varieties, namely, *X1730A*, grown in the south, and Domain Sakel, grown in the north, was insignificant. There were also highly significant seasonal differences. Because of the established effect on Gezira cotton yields[6] of rains falling between July 1 and August 15 (pre-sowing rains) the covariance of concentration of leaf nitrogen on these rains was examined during the six seasons when all the cotton had been sprayed with DDT. The correlation coefficient of concentration of leaf nitrogen on pre-sowing rains was − 0·5842 which, for 22 degrees of freedom, is highly significant. There was evidence, however, that the effect was not direct, and seasonal variation in concentration of leaf nitrogen was caused by some uninvestigated factor itself correlated with rainfall.

The regression of the mean September and October concentration of nitrogen in the leaf material of the cotton plant on pre-sowing rains could be expressed by the equation:

$$X_2 = 4·07 - 0·0031X_1$$

where X_2 is the mean concentration of leaf nitrogen during September and October (as percentage of dry matter), and X_1 is the rainfall in mm. during July 1–August 15. The standard error of the regression coefficient is ± 0·0009).

The seasonal incidence of pests feeding on the leaves was recorded during four seasons at one site (Gezira Research Farm), and was found to be correlated with pre-sowing rains and the concentration of leaf nitrogen. The regression equation for rate of jassid increase is:

$$a = 18·03 - 0·071X_1\ (\pm 0·010)$$
$$a = 10·96X_2\ (\pm\ 0·69) - 35$$

where a is the mean rate of increase in jassid nymphs per 100 leaves per day

(other symbols as before, with standard errors of regression coefficients in brackets). This describes the rate of increase during September and October before spraying as well as that during October and November after DDT spraying.

The mean infestations during October and November, namely, after spraying, and at a time when the pests are considered to exert most effect on crop yields, were:

Jassids : $Y_1 = 156\cdot4X_2 - 478\ (\pm\ 20\cdot4)$

Whitefly : $Y_2 = 9\cdot71X_2 - 0\cdot27\ (\pm\ 0\cdot17)$

Thrips : $Y_3 = 4\cdot16X_2 - 0\cdot89\ (\pm\ 3\cdot17)$

where Y_1 is the mean number of nymphs of *E. libyca* per 100 leaves, Y_2 is the mean number of adults of *B. tabaci* (logarithm), and Y_3 is the percentage of leaves infested with larvæ of *Hercothrips* sp. (arc sin/percentage) (other symbols as before).

The regression coefficients for whitefly and jassid infestations were highly significant : that for thrips was not significant.

E. libyca is preyed upon by the Mymarid egg parasites *Anagrus* sp. and *Paranagrus* sp. while the *Aphelinid* parasites *Eretmocerus* sp. and *Prosaptella* sp. cause heavy mortality of the later instars of *B. tabaci*. All these parasites appear to be more numerous in seasons of good than of poor pre-sowing rains, but statistical evidence is deficient.

The results, although incomplete, raise the interesting possibility that the cotton plant in the Sudan Gezira may, by the seasonal changes in composition of its foliage expressed by percentage of Kjeldahl nitrogen, influence the rate of increase of some of its leaf-feeding insects in such way as to enable them to 'break away' from biological controlling agents. According to F. Crowther[7] the concentration of nitrogen in cotton leaves is determined by : (1) the concentration of nitrogen in the soil and (2) the rate of development of the plant. Jewitt[8] showed that the nitrate nitrogen in Gezira soils was negatively correlated with pre-sowing rains. The results so far available do not indicate that rains control leaf nitrogen directly, but determine it through other correlated factors influencing the early rate of development of the cotton plant.

It is hoped that this knowledge, considered in relation to some other aspects of the ecology of the pests concerned, will enable prediction to be made of pest outbreaks in the Sudan Gezira before the crop is sown. A full account of this approach in relation to the cotton jassid will be published elsewhere.

I am grateful to Sayed Ahmed Kordofani, of the Research Division, for access to his records of the growth and composition of the cotton plant in the Sudan Gezira, and to the Chief of Agricultural Research, Ministry of Agriculture, Sudan Republic, for permission to publish this work.

Bat Erosion as a Factor in Cave Formation

I have read with much interest the communication by W. A. King-Webster and J. S. Kenny[1] in which it is suggested that roosting bats can play a considerable part in cave excavation where the rock is soft. In particular, reference is made to the existence, in the roof of a limestone cave in Mt. Tamana (Trinidad), of bell-shaped cavities ranging in depth from 3 ft. to 6 ft., and in diameter at the mouth from 1½ ft. to 2½ ft., and which are used by sleeping bats. The suggestion is made that the habit of the bats of alighting at the lower edge of the bell and then jostling upwards into a central position, by continuation over innumerable years, has led to the excavation of these cavities, with maximum removal of rock at the mouth of the bell.

Ceiling cavities of the type described are, however, a commonplace feature in many limestone caverns, and indeed in portions of those caverns that have never been known to have been used by bats. This applies particularly to tunnels so far in linear distance from the cave entrance or in depth below it that they are beyond the normal zone of penetration of the bats. Such ceiling pockets, and also similar indentations in cave walls, have been described by Bretz in his classic paper[2], in which he elaborates on the theories, originally proposed by Davis[3], concerning the phreatic origin of certain types of cave tunnels and systems. Bretz specifically quotes such wall and ceiling pockets as examples of cave features of phreatic origin, pointing out that it is difficult to visualize their formation by any solution mechanism under conditions whereby there was an air space above the water surface. He therefore considers that such ceiling pockets were formed below the lowest normal water-table level (such as might occur at times of drought) and he directs attention to the fact that if the 'eating-out' process is continued long enough, adjacent pockets merge into one another, thus producing one of the effects described by King-Webster and Kenny.

During the course of the studies made by my wife and myself on the habits of certain cave-dwelling bats[4], in particular, the greater horseshoe bat (*Rhinolophus ferrumequinum*), we have often noticed ceiling pockets, of the type described above, in the natural caverns that exist in scattered outcrops of Devonian limestone, in the neighbourhood of Buckfastleigh in Devon. Some of these pockets are commonly used during the winter months by the greater horseshoe bats, probably because such dome-shaped cavities provide areas of roof that are free from draughts. It is, however, important to note that these caves were only revealed as a result of quarrying operations during the past century, and they were thus not occupied by bats until they were opened to the outside world, barely a hundred years ago. Although we have evidence in Devon that the claws of a greater horseshoe bat can mark the roof of a cave, at least to the extent of scratching off powdery surface deposits from the limestone, it would be surprising indeed if the colonies of bats could have excavated roof pockets to a depth of several feet in such a limited time. I therefore feel that although the 'bat erosion' effect postulated by King-Webster and Kenny may well occur with certain types of limestone, it represents at best only a secondary, and probably minor, contribution to the shape and size of the ceiling pockets described.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 24

Royal Geographical Society (at 1 Kensington Gore, London, W.7), at 5 p.m.—Lieutenant C. J. Wynne-Edwards, R.N.: "Hydro-aphic Survey in the Falkland Islands Antarctic Dependencies".

British Society for the History of Science (in the Council oom of the Science Museum, Exhibition Road, South Kensington, ondon, S.W.7), at 5.30 p.m.—Dr. G. J. Whitrow: "The Evolution Our Numerals and System of Numeration".

Institution of Electrical Engineers, Radio and Telecom-unication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—r. J. S. Seeley and Dr. J. Brown: "The Use of Dispersive Dielectrics a Beam-Scanning Prism"; Dr. J. S. Seeley: "The Quarter-Wave atching of Dispersive Materials"; Mr. A. Carne and Dr. J. Brown: Theory of Reflections from the Rodded-Type Artificial Dielectric".

University of London (in the Anatomy Theatre, University ollege, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. C. A. ogers: "Packing and Covering".* (Inaugural Lecture.)*

Royal Aeronautical Society (at the Institution of Civil Eng-eers, Great George Street, London, S.W.1), at 6 p.m.—Mr. J. E. ateman: "Inertia Guidance".

Tuesday, November 25

Institution of Chemical Engineers (at the Geological Society, urlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. H. E. ose: "A Suggested Equation Relating to the Mixing of Powders d its Application to the Study of the Performance of Certain Types f Machine".

University of London (at the London School of Hygiene and ropical Medicine, Keppel Street, Gower Street, London, W.C.1), 5.30 p.m.—Dr. E. H. Mercer: "Electron Microscopy and the ructure of the Living Cell".* (Eighth of eleven lectures on "The ientific Basis of Medicine" organized by the British Postgraduate edical Federation. Further lectures on November 27 and December and 4.)

Society of Instrument Technology, Data Processing Section t Manson House, Portland Place, London, W.1), at 6 p.m.—Mr. C. M. Barnes: "Digital Data-Recording for Nuclear Experiments".

Society for Analytical Chemistry, Physical Methods Group t the Chemical Society, Burlington House, Piccadilly, London, .1), at 6.30 p.m.—Fourteenth Annual General Meeting, followed y meeting on "Modern Methods of Purification".

Wednesday, November 26

University of London (at the Postgraduate Medical School of ondon, Ducane Road, London, W.12), at 2 p.m.—Dr. H. M. Sinclair: Essential Fatty Acids".*

Geological Society of London (at Burlington House, Piccadilly, ondon, W.1), at 5 p.m.—Mr. Graham F. Elliott: "Fossil Calcareous lgal Floras of the Middle East"; Miss Leonora A. Stevens: "The nterglacial of the Nar Valley, Norfolk" (paper communicated by r. R. G. West).

Royal Geographical Society (at 1 Kensington Gore, London, W.7), at 5 p.m.—Prof. Max Mallowan: "Excavations at Nimrud, 958".

Institute of Marine Engineers (at the Memorial Building, 6 Mark Lane, London, E.C.3), at 5.30 p.m.—Sir John Cockcroft, M., F.R.S.: "Recent Advances in Nuclear Engineering" (Sir harles Parsons Memorial Lecture).

Institution of Electrical Engineers, Supply Section (at avoy Place, London, W.C.2), at 5.30 p.m.—Dr. L. L. Alston and rof. F. M. Bruce: "Investigations of Power-Follow Current Phe-omena using a Synthetic Power Source"; Dr. L. L. Alston: "The mpulse Initiation of Arc Discharges".

British Institution of Radio Engineers (at the London School Hygiene and Tropical Medicine, Keppel Street, Gower Street, ondon, W.C.1), at 6 p.m.—Annual General Meeting. 7.15 p.m.—rof. E. E. Zepler: Presidential Address.

Society of Chemical Industry, Food Group (at 14 Belgrave quare, London, S.W.1), at 6.15 p.m.—Scientific Papers.

British Psychological Society, Medical Section (at the Royal ociety of Medicine, 1 Wimpole Street, London, W.1), at 8.30 p.m.—r. John Bowlby: "Studies of Parent–Infant Interaction in Man nd Animals—some Notes on Projects in Progress".

Thursday, November 27

Institute of Physics, Electron Microscopy Group (at the Royal ociety of Arts, John Adam Street, Adelphi, London, W.C.2), at 0 a.m.—Meeting on "Electron Staining".

University of London (at the London School of Hygiene and ropical Medicine, Keppel Street, Gower Street, London, W.C.1), at .30 p.m.—Mr. Michael Abercrombie: "Cell Surface and the Control Growth".* (Ninth of eleven lectures on "The Scientific Basis of edicine" organized by the British Postgraduate Medical Federation. urther lectures on December 2 and 4).

Friday, November 28

Institute of Physics, Electron Microscopy Group and X-Ray nalysis Group (at the Institution of Civil Engineers, Great George treet, London, S.W.1), at 10 a.m.—Joint Conference on "Precipita-on in Alloys".

Institute of Rural Life at Home and Overseas (at Friends International Centre, 32 Tavistock Square, London, W.C.1), at 1.15 p.m.—Mr. George Bredin: "The Impact of the Gezira Cotton-Growing Scheme on the Rural Population of the Blue Nile".*

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Turbidity Currents: High Speed Underwater Flow of Sediment Suspensions". Chairman: Dr. G. E. R. Deacon, F.R.S. Speakers will include Dr. A. S. Laughton, Dr. R. Stoneley and Dr. T. H. Ellison.

Physical Society (in the Large Lecture Theatre, Chemistry Department, Imperial College, Imperial Institute Road, London, S.W.7), at 5 p.m.—Prof. Niels Bohr, F.R.S.: "General Implications of the Atomic Nucleus" (9th (1958) Rutherford Lecture).*

Royal Anthropological Institute of Great Britain and Ireland (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Sir Wilfrid Le Gros Clark, F.R.S.: "Bones of Contention" (Huxley Memorial Lecture).

Institution of Electrical Engineers, Medical Electronics Discussion Group (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion Meeting on "Problems Encountered in the Field of Neurophysiology".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. Z. Young, F.R.S.: "Squids, Cuttlefishes and Octopuses".

Friday, November 28—Thursday, December 4

Electronic Computer Exhibition (at Olympia, London, W.14).*

Monday, December 1—Wednesday, December 3

Business Computer Symposium.

Saturday, November 29

Institute of Physics, X-Ray Analysis Group (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 9.30 a.m.—Scientific Papers.

Botanical Society of the British Isles (in the Lecture Room of the Royal Horticultural Society, Vincent Square, London, S.W.1), at 12 noon—Exhibition Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer, Grade B (with a degree in electrical engineering or physics and preferably a special knowledge or industrial experience of some branch of the subject), in Telecommunications and Electronics—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (November 28).

Assistant Lecturer (with an honours degree in physics and preferably able to teach the subject to a high standard) in Physics—The Principal, Wigan and District Mining and Technical College, Wigan (December 1).

Lecturer or Assistant Lecturer (with a good honours degree and teaching experience) in Biology at the Royal Technical College of East Africa—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (December 5).

Lecturer (with special qualifications in botany or agricultural botany) in Botany—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (December 5).

Lecturer or Research Assistant in Bacteriology and Virology—The Registrar, The University, Sheffield (December 6).

Research Assistant (preferably with a Ph.D. degree and suitable experience in biochemistry and microbiology) in the Department of Bacteriology, to assist in a programme of work on the immunochemistry of *Bordetella pertussis*—The Registrar, The University, Manchester 13 (December 6).

Senior Lecturer and a Lecturer in Mathematics at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, December 12).

Lecturer (graduate in metallurgy or chemistry with special qualifications in the theory and principles of extraction metallurgy) in Metallurgy—The Registrar, The University, Manchester 13 (December 13).

Senior Lecturer/Lecturer in Chemistry at the University of New South Wales, Sydney, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (Australia, December 13).

Reader in Aeronautics at Imperial College, London, S.W.7—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 15).

Senior Lecturer (registered pharmaceutical chemist) in Pharmacy at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 15).

Chair of Civil Engineering, Senior Lecturer or Lecturer in Mechanical Engineering, Lecturer in Engineering Mathematics, Lecturer in Civil Engineering, and a Lecturer in Electrical Engineering at the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 29).

Chair of Botany—The Registrar, The University, Hull (December 31).

Research Fellow in the Physiology Department, Faculty of Rural Science, University of New England, Australia, to undertake research associated with a study of the comparative physiology of mammalian erythrocytes with particular reference to the physiological significance of individuality in the ruminant erythrocyte—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 31).

LECTURERS OF ASSISTANT LECTURERS IN PHYSIOLOGY at the University of Malaya—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

LECTURER OR ASSISTANT LECTURER (preferably with qualifications in mathematical analysis and/or statistics) **IN MATHEMATICS** at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 10).

LECTURER IN PURE MATHEMATICS—The Secretary, Queen's University, Belfast (January 15).

BROTHERTON CHAIR OF CHEMICAL ENGINEERING in the Houldsworth School of Applied Science—The Registrar, The University, Leeds 2 (January 31).

ENTOMOLOGIST (with a good honours degree in zoology and an interest in, and aptitude for, taxonomic work, and preferably experience in the Diptera particularly the Calyptrata) at the Commonwealth Institute of Entomology, London—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (January 31).

BIOCHEMIST (with a Ph.D. degree or equivalent research experience), for work on the metabolism of cell and organ cultures—The Secretary, Strangeways Research Laboratory, Wort's Causeway, Cambridge.

EXPERIMENTAL OFFICER (at least 26 years of age, preferably with a pass degree, or at least H.N.C. (engineering or applied physics) or equivalent), to carry out experiments designed to investigate the mechanical strength of complex assemblies, to instrument parts for experiments and to analyse experimental results—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. A.1895/34.

PHYSICAL CHEMIST, PHYSICIST OR METALLURGIST, for research on anodic oxide films—Dr. G. M. Shrum, Director, British Columbia Research Council, University of British Columbia, Vancouver 8, B.C., Canada.

READER IN NUCLEAR ENGINEERING at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1.

RESEARCH ASSISTANT (preferably with a Ph.D. degree in chemistry or biochemistry, for work on the biochemical analysis of *Haemophilus pertussis* antigens—The Secretary, The Lister Institute of Preventive Medicine, Elstree, Hertfordshire.

RESEARCH ASSISTANT, to help with quantum mechanical calculations on tetrahedral and other nearly spherical molecules, using an electronic computer—Dr. R. A. Buckingham, University of London Computer Unit, 44 Gordon Square, London, W.C.1.

RESEARCH FELLOW (with experience in acoustic measuring techniques) **IN PHYSICS**, for work on materials for use in acoustic assemblies—The Registrar, The University, Leicester.

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (honours graduate with a first- or good second-class honours degree), to undertake research on ceramic fuels for reactors, including the determination of physical and chemical properties over a wide range of temperatures, phase equilibria and investigation of fabrication techniques—The Group Recruitment Officer (1248/34), U.K.A.E.A., Atomic Energy Research Establishment, Harwell, Berks.

SENIOR RESEARCH OFFICER (PLANT PATHOLOGY) (with a good honours degree in botany (plant pathology) and suitable professional and administrative experience), to take charge of the Plant Pathology Division, Department of Agriculture, Kenya, and to guide and direct work of other pathologists in the Division—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/7/015.

SENIOR TECHNICIAN (capable of supervising setting-out of laboratories for physiological, biochemical and histological classes, and a knowledge of workshop techniques) **IN THE PHYSIOLOGY DEPARTMENT**—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

CHOLESTEROL

by DAVID KRITCHEVSKY
(University of Pennsylvania)

300 pages *Illustrated* *78s. net.*

This book provides a centralized source of information on the biological function and significance of cholesterol. Gathering together pertinent material which has been dispersed throughout the chemical and medical literature, the book is not just a collection of special chapters, but a unified work.

★ *Reinhold Publishing Corporation Books* ★

New Titles in the Plastics Applications Series

EPOXY RESINS

by I. SKEIST

306 pages *Illustrated* *44s. net.*

The author clearly describes the uses of these versatile new materials as casting and potting compounds, adhesives, and plasticizers. The reader is also provided with the reasons behind each formulation.

GUM PLASTICS

by M. S. THOMPSON

204 pages *Illustrated* *36s. net.*

The first extensive treatment of rubber-modified plastic resins and their uses. It emphasizes the applications of impact-polystyrene, ABS polymers, and impact PVC, and covers the general properties, chemistry, and fabrication of these compounds.

PRECISION INSTRUMENTS

Refractometers for Industry and Research

Our well-known standard Abbe type refractometer has a refractive index scale on glass and is read by transmitted light, thus leading to greater convenience in taking measurements and a higher degree of accuracy.

The instrument as illustrated is supplied with degree scale arc and micrometer screw reading directly to 10 seconds, corresponding to a refractive index accuracy within 0.00005. Conversion tables for use with sodium light are supplied.

Full particulars sent on application.

We shall be pleased to demonstrate these instruments and give any advice within our power, if you will call at our Works

TREASURY CONTROL AND SCIENTIFIC RESEARCH

IT has been apparent for some years, both from continued questions in the House of Commons and from the reports of the Select Committee on Estimates and the Committee of Public Accounts, that the House of Commons is increasingly concerned about the expenditure of the Department of Scientific and Industrial Research and of the University Grants Committee. The criticism advanced has not been unfriendly, for there has been no indication that Parliament wishes to restrict expenditure on scientific and industrial research; on the contrary, it is generally recognized that this should be expanded but that more care should be taken to ensure that full use is made of the results of such research. The Treasury has stoutly defended the autonomy of the universities and refused to agree to any proposals that appear likely to endanger their independence and freedom to determine the nature and balance of their work, and the reorganization of the Department of Scientific and Industrial Research, following the report of the Jephcott Committee, may be regarded as a sequel to some Parliamentary criticism of the Department.

Although the Treasury has made some concessions in regard to the expenditure of the Vote for the Department which give more freedom for the planning of research over a period of years, it would not appear that the problem of the control of expenditure on research, even in general terms, is fully understood by Parliament. A recent report from the Select Committee on Estimates (see *Nature*, October 25, p. 1111, and November 1, p. 1181), which was devoted to the work of the establishments of the Department, showed a concern with expenditure, particularly with the recovery of expenditure from those who had benefited by it, which could well prejudice the planning and support of the Department's programmes of research and even warp their direction. Furthermore, although the third report from the Committee of Public Accounts for the session 1957–58 fully exonerated the consulting engineers for the Jodrell Bank radio-telescope from failure to consult with the University professor in charge of the project, it is disturbing that the Committee should have advanced its criticism last session without inviting evidence from the University of Manchester or from the consulting engineer in charge of the building project. To say the least, the Committee of Public Accounts has shown little awareness of the dangers of waste and delay which may arise in such undertakings from the too rigorous application of financial accounting through estimates.

The latest report, while admitting that the previous report was ill-informed, gives no clue as to why and where the Committee regards the financial control exercised over the scheme as unsatisfactory. It welcomes the assurance that the remaining money required for the construction of the telescope will not be met, directly or indirectly, from public funds, but will be found from other sources by the University (see p. 1484 of this issue). There is no evidence that public money has not been properly and openly spent on the project, and equally no recognition of the difficulty of providing in advance firm estimates of cost for the construction of such novel equipment.

This is the most disturbing aspect of the report from the Committee of Public Accounts. It is vital that this affair should not deter other universities from entering on big building projects, or discourage the Department of Scientific and Industrial Research from its statutory duty of fostering fundamental research. Scientific research has come increasingly to depend on expensive equipment, the construction of which is often as much beyond the resources of individuals as it is beyond their capacity, without co-operation from others, to keep it fully and economically employed. As already noted, there appears to be a danger that the Estimates Committee may also divert the Department from the most fruitful discharge of its responsibilities.

Nor can we regard the danger as likely to be eliminated entirely if greater efforts are made in the matter of publication either through annual reports or in other ways. Attention to some comments of the Estimates Committee on this point should go some way to avoid unhelpful and misinformed criticism in Parliament, and might well provide the most effective solution to the real problem of public accountability. The reports of these two Parliamentary Committees demonstrate the urgency of this issue; but they equally show how imperfect and inadequate either the Committee of Public Accounts or the Select Committee on Estimates is as an instrument for the control of expenditure on such matters as research and development, though, as Basil Chubb showed clearly in his study of these Committees, that is not their function.

The whole question of Treasury control was examined by Prof. S. H. Beer in a thoughtful study published two years ago. He was not concerned with the practical aspect of its appropriateness to the needs of to-day, but, for the reasons just given, the more limited examination of Treasury control of expenditure in the sixth report from the Select Committee on Estimates for the session 1957–58[*] is of profound interest to the scientist and technologist at the present moment. Primarily the report is concerned with the methods of Treasury control employed and their effectiveness, rather than with actual expenditure, with the view of discovering whether they are such as to ensure economies in the Estimates, and attention is concentrated on control over supply expenditure, in contrast to establishment expenditure, which the Committee considers should be further examined. The latter relates to all expenditure on personnel remunerated from public funds, and since supply expenditure covers

[*] Sixth Report from the Select Committee on Estimates together with the Proceedings of the Committee, Session 1957–58: Treasury Control and Expenditure. Pp. 42. (London: H.M. Stationery Office, 1958.) 2*s*. net.

all other types of expenditure, it includes that on new projects such as the Jodrell Bank radio-telescope. This is nowhere discussed in the report; but for the scientist and technologist, one of the most important sections is that which discusses the way in which the Treasury exercises control by prior sanction of new projects and how it functions in practice.

First, it is important not only to scrutinize new policies but also to review carefully current policies. The Committee recognizes that it is uneconomical to cut a good new policy while a less-worthy policy is allowed to carry on without modification; but it found little to suggest that established policies are sufficiently reviewed and is disturbed at the absence of evidence of a constructive approach which would ensure that the reasons for continuing a policy or programme were independently and systematically sought. This is particularly important in regard to scientific and technological research, and it is in line with criticism from the Committee of Public Accounts and elsewhere that the Estimates Committee recommends that the Treasury should ensure that established policies in the civil field are more systematically reviewed.

It might well be asked whether this should be the function of the Advisory Council for Scientific Policy, or, in matters of defence research, of the Defence Research Policy Committee; and that could also apply to the second matter on which the Committee expresses concern. While it appreciates the difficulty of accurately estimating the cost of a novel policy or of research or development on a totally new type of weapon, and welcomes the appointment of a committee to consider and make recommendations about methods of managing and controlling research or development projects as likely to lead to more accurate estimating in this field, it rightly insists that sound decisions can only be taken on the basis of accurate estimates. The Committee suggests that supplementary estimates, due to the practice of under-estimating, can largely destroy effective budgetary control both of the national economy and of Government expenditure.

The third matter that caused the Estimates Committee some concern is the natural tendency, within the present annual system of Estimates and Accounts, to concentrate too much attention on the policy and expenditure proposals for the coming financial year, with too little regard to the commitments and consequences for future years. Such obsession can stultify forward planning, and it is the more serious in the context of the tendency to under-estimate the costs of policies and major projects. While the Ministry of Defence and the Treasury have recently introduced a practice of preparing—each summer—forecasts for three years ahead, on the basis of current policy, of the total and major features of defence expenditure, the Committee is disappointed that there seems to be little parallel effort on the civil side. Forecasts alone are not enough, though the defence forecast for the next year, when approved by the Government, becomes the defence budget on which that year's estimates are based; and the Committee urges that such a dynamic approach to expenditure should also be made in the civil sector.

In discussing next the way in which Treasury control operates over programmes of expenditur and annual estimates, the Estimates Committe appears to recognize fully that it is necessary fo certain purposes, such as university grants or the Department of Scientific and Industrial Research, to allocate expenditure for several years ahead, and i endorses the increased departmental responsibility which is involved in such a practice. It suggests however, that in some fields programmes might be made more specifically schedules of work to be done and that while the department is probably the bes judge of priorities, the need for capital works should be justified to the Treasury. Without making specific recommendations, it suggests that such specific programming might offer advantages in major research and development work where needs can be anticipated

A large part of the Committee's inquiry was devoted to hearing evidence about the merits of the control which the Treasury exercises by prior sanction of new projects, its effectiveness in achieving economies and the degree to which financial authority could be and has been delegated to spending departments. In view of the high proportion of Government expenditure which is now required for highly technical projects, the Estimates Committee rightly attaches great importance to these questions. Under the traditional system, such projects are not vetted by any technical officer except those responsible for initiating them, and it is obvious that the Estimates Committee has grave doubts as to the effectiveness of prior sanction control by the Treasury.

The Treasury does not employ professional or technical experts, and the value of such control depends accordingly largely on the skill with which the Treasury officer can criticize a proposal submitted by departmental officers who may have spent their entire working lives dealing with that subject, or a highly technical project submitted by a technical expert. Such lay critics are not necessarily ignorant—and the educational system could reduce the risk of them being so—and it may well be beneficial to require the expert to justify his claim for money to a man of general common sense and broad understanding. Nevertheless, the Treasury critic may wel feel inhibited in some circumstances, and be limited to judging whether a need is proved. The Committee found little indication that Treasury scrutiny made departments less meticulous than they should be in their own scrutiny, but it points out that this reliance on laymen encourages, and certainly makes possible attempts to blind the Treasury with science in relation to some types of project. It does not think that the method will work unless technical men play their part in discussions with the Treasury, and recommends accordingly that more attention should be paid to the advantages of associating technical officers with financial decisions. It is rightly observed that an awareness by technical officers of the financial implications of their proposals is an essential feature of a system which places a large measure of economic responsibility within spending departments.

The Estimates Committee does not, however, suggest the abandonment of control by prior sanction entirely, though it recommends some relaxation of its exercise, particularly when the expenditure is part of a specific policy decision approved by the Cabinet or Treasury or is a matter of detailed administration, or again when the raising of the financial ceiling will not remove a major field of departmental expenditure from Treasury control. It suggests that control could also be relaxed where greater use is made of the technique of control of expenditure by programmes as already indicated ; but it also points out that there are highly important and far from standard projects where inaccurate estimates are frequently made, and the Treasury has shown that its scrutiny can lead to economies, of which the Treasury is not seeing enough.

While on balance the present system appears to work reasonably well, and it is probable that much more expenditure is wasted through political decision or indecision than from the weaknesses which are noted by the Estimates Committee, on the evidence already discussed the Committee appears to be fully justified in its recommendation of a full inquiry into the theory and practice of Treasury control of expenditure. What is debatable is whether the small independent committee, with access to Cabinet papers, which it recommends will suffice, or whether the inquiry should not rather be entrusted to a Royal Commission. To the question whether the existing practice is as effective as modern conditions demand, it gives no definite answer, although it makes a number of suggestions for improving the system.

Some of these have already been noted, and others are made in considering the Treasury's interest in continuing expenditure, where the Committee again points out the danger that Supplementary Estimates or increases may divert attention from areas of expenditure which should be decreasing because of reduced demand, or because the costs of running an established service are lower than those of initiating it. While it recognizes that Supplementary Estimates are no longer regarded as discreditable, no positive proposals are made for dealing with this difficulty, which so far as the technical projects are concerned might well involve bringing technical experts into the Treasury, much as has been done in the Organization and Methods Division, and possibly developing a Division competent to say which new increases in departmental expenditure should be offset by new economies and which covered by Supplementary Estimates. Such a device might well have avoided the difficulty over the radio-telescope at Jodrell Bank, and need not involve serious delays.

For the rest, the Estimates Committee emphasizes the undesirability of leaving all initiative for economy to the departments, and the value of continuing Treasury interest. It is not satisfied, for example, that the Treasury takes sufficient interest in how grants-in-aid are spent or the services administered—apparently the attack on the University Grants Committee is only suspended. On research and development for defence purposes, it recognizes both the difficulty of control and the effect on the demand for skilled man-power and the critical resources of industry. The estimated expenditure for research and development by the Ministry of Supply alone this year exceeds £211 million, and it is vital to get the balance of effort right. With the pressure of demand on limited resources, it is not enough to examine new projects. Research and development programmes also require regular and careful combing to remove projects which have proved abortive and also those that have already produced most of the results that could be expected of them.

The crucial question is how such scrutiny and pruning are to be effected. Inevitably the Treasury relies chiefly on the scientific advisers to the departments, and the Chief Scientist of the Ministry of Supply said that the biggest and most effective action in reviewing research came from the pressure on scientific branches and establishments to do more and more tasks with limited funds and man-power. In consequence, they were always reviewing programmes and cutting out anything that did not seem to be sufficiently profitable. In other words, the pruning of projects is best undertaken by those responsible for the projects ; but their views may be too narrow, and accordingly reviews by the Defence Research Policy Committee or, in the civil field, the Advisory Council for Scientific Policy, are also desirable. The investigation now being made by Sir Claud Gibb's Committee may result in the Treasury becoming better equipped to judge the value of defence research and development work that has already been authorized ; but the Estimates Committee's report does not suggest that however effective Treasury control may become it will eliminate the need for such co-ordinating bodies.

The Estimates Committee's report indeed leaves grave doubts as to whether, in fact, either the Defence Research Policy Committee or the Advisory Council for Scientific Policy is functioning effectively. It is on bodies of this character that we must rely for the wide and expert views which can ensure that the scientific and technical effort of Britain is in balance, and that the demands on man-power and resources as well as on finance made by one sector are not out of proportion or impeding vital effort elsewhere. There, if anywhere, should be awareness that no country to-day can undertake every scientific or technological project at once. How this co-ordination is to be effected is a problem of the first magnitude to which urgent attention should be given. Some of the proposals of the Estimates Committee may help, but a fundamental condition of effective control will remain a real public understanding in Parliament, in the Government, in the Civil Service and among the general public of the nature and needs of scientific and technological work. To that a sound and effective publication policy could contribute, but the decisive factor in the end will be the development of an educational system adequate to the needs of a changing technological age.

ENCYCLOPÆDIA STATISTICA

The Advanced Theory of Statistics

By Prof. Maurice G. Kendall and Alan Stuart. Vol. 1 : Distribution Theory. (Three-volume edition.) Pp. xii+433. (London : Charles Griffin and Co., Ltd., 1958.) 84*s*.

FIFTEEN years ago, Prof. M. G. Kendall published the first of two volumes that rapidly established themselves as indispensable to statisticians. Even critics who disagreed with some of the controversial views expressed and found flaws in points of detail not only were bound to admire Kendall's versatility in his comprehensive coverage of mathematical statistics but also came to accept the books as standard works of reference. These fifteen years have seen consolidation in some fields, reduction of emphasis in others, new lines of theory, and above all new understanding of the inter-relations between parts of the subject. In the preparation of a completely revised and re-set edition, Prof. Kendall has had Mr. A. Stuart as collaborator. This edition is to appear in three volumes ; the magnitude of the task can be appreciated from the fact that Vol. 2, "Statistical Inference and Statistical Relationship", is planned for publication in 1960, and for Vol. 3, "Statistical Planning and Analysis, and Time Series", no date has yet been given.

Evaluation of one volume alone is unsatisfactory, because the balance of the whole work cannot be judged. The first twelve chapters are essentially the same as the first eleven chapters in the previous Vol. 1, but have many sections improved in rigour or brought up to date. Frequency-generating functions, a surprising omission previously, are now employed to good advantage. Changes of emphasis on systems of distributions are typified by the virtual omission of the Charlier type-*B* series and the inclusion instead of a good summary of the lognormal distribution and Johnson's transformations. The presentation of the calculus of probabilities is now much clearer ; statement of the weak and strong laws of large numbers is one aspect of its improved coherence, yet the authors' practical contention that "In statistics it is a mark of immaturity to argue overmuch about the fundamentals of probability theory" is well maintained. In many places, as in the discussion of distributions of ratios of statistics, groups of related topics are better integrated than before. The long account of *k*-statistics and symmetric functions, inevitably somewhat tedious reading to those who lack special interest in it, is none the less an excellent account of a subject to which Kendall has himself made outstanding contributions ; formulae appropriate to finite populations are now included, and the new Chapter 13 develops generalizations to bivariate distributions.

Since publication of the first edition, one major growth of statistical theory has been in connexion with order statistics and non-parametric analysis. The ultimate importance of this work to statistical thought cannot yet be assessed, but an excellent survey of its main themes rightly appears as a new chapter. A good account of multivariate normal theory from a modern point of view forms Chapter 15, and a final chapter summarizes the derivation and properties of the main distributions associated with the normal.

Although courses of instruction in statistical theory can well be based upon this book, as an aid to which more than 300 exercises (mostly fairly difficult) are included, a majority of statisticians will probably value it and its successors chiefly as an encyclopædia. Not only are the main lines of development of theory clearly presented, but also the authors embroider their account with mention of many topics of lesser importance ; to have these recognized and made more accessible than in past volumes of journals adds greatly to the interest and value of "Kendall and Stuart" as a work of reference. Indeed, my own regret is that space has not been found for a still greater range of minor themes : references to books and papers listed in previous editions but now excluded as falling outside the stream of current statistical thought could still have been justified for encyclopædic purposes. One fault, perhaps inevitable in an encyclopædia, is the emphasis on facts and the comparative neglect of discussion of the circumstances in which these facts are useful. The sections on χ^2, for example, are still somewhat perfunctory, and no reader would guess from them that the uses of this statistic in the analysis of observational records are so diverse.

Prof. Kendall has placed all statisticians in his debt for the breadth of his publications during the past fifteen years ; the next two volumes in this series will be awaited with interest and with the hope that all will continue to be so conscientiously revised as statistical theory continues to grow. D. J. Finney

THE SCATTERING OF LIGHT BY SMALL PARTICLES

Light Scattering by Small Particles

By H. C. van de Hulst. (Structure of Matter Series.) Pp. xiii+470. (New York : John Wiley and Sons, Inc. ; London : Chapman and Hall, Ltd., 1957.) 96*s*. net.

THE problem of the scattering of electromagnetic radiation by a homogeneous sphere, to which partial solutions in particular cases were provided by Rayleigh and others towards the end of last century, was finally solved by Mie in 1908. The application of the formal Mie solution presents great difficulties. The series in which it is expressed may converge slowly, and the investigator who seeks to apply the formula to a particular problem is therefore fortunate if he finds ready-made tables or curves for the scatter functions relevant to the refractive index and ranges of the ratio of radius to wave-length with which he is concerned.

It was in 1945, while Dr. H. C. van de Hulst was investigating the effects of interstellar dust, that he became aware of these difficulties and was led first to undertake a thorough review of the literature and then to make important contributions himself, both to the theory and to filling the gaps by new computations. In this valuable book, he has assembled in an admirably clear and logical manner the results of his work of reviewing, and of his own further independent studies of, this very complex subject.

Van de Hulst confines himself to the theory of 'independent scattering', that is, to the scattering by particles sufficiently distant from each other that "for all practical purposes, the intensity scattered by the various particles must be added without regard to phase". It appears that separation by a distance as small as three times the radius yields independent scattering; actually, in a dense fog, the mutual separation is of the order of twenty times the radius of the droplets. He imposes the further limitation that 'single scattering' alone is considered, the criterion for this (that is, for the absence of 'multiple scattering') being that doubling the concentration of particles in a sample doubles the scattered intensity.

The first of the three parts into which the book is divided is concerned with the development of general theorems for scattering by particles of arbitrary size, shape and composition.

The second part provides the theory necessary for the calculation of the scattering for a wide variety of special particles large and small compared with the wave-length, absorbing and non-absorbing, and of various shapes. This is by far the largest and most important part of the work and is the section that is certain to be widely consulted by applied scientists seeking aid with numerical calculations. Nearly every chapter contains new formulæ and numerical results, and a valuable bibliography of numerical computations by the Mie theory is provided. There is an excellent chapter on the optics of a raindrop which includes a penetratingly critical review of theories of the rainbow and a full account of the theory of the glory, extended in a later chapter by a brief examination of the effect of the existence of surface waves.

The final part of the book consists of four short chapters on the practical application of the theory to the explanation of scattering phenomena in the domains of chemistry, meteorology and astronomy, and on the use of scattering and extinction measurements to derive estimates with varying accuracy of refractive index, size and distribution of sizes, shape and orientation, and chemical composition of the particles.

A valuable feature of this outstanding book, which should be the standard work for many years, is the comprehensive list of carefully annotated references at the end of each chapter. JAMES PATON

COMPLEXOMETRIC ANALYSIS

The Analytical Uses of Ethylenediamine Tetraacetic Acid

By Prof. Frank J. Welcher. Pp. xvii+366. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.) 64*s*.

AN important development in chemical analysis during recent years has been the application of aminopolycarboxylic acids, especially ethylenediamine tetraacetic acid, as complexing agents. Many publications concerning the analytical uses of this acid have appeared, and Prof. Welcher's book provides a summary of information gleaned from the 963 bibliographical references listed at the end.

The author states that he has endeavoured to collect information from all papers describing the use of ethylenediamine tetraacetic acid in inorganic analysis, but that critical evaluation of each method has not been attempted and that the book is not intended as a manual of recommended methods, though details of many procedures are given with reports on interference, optimum conditions, and claims as to accuracy.

The book opens with a discussion of general principles, including complex-formation constants, titration methods, colorimetric determinations, and the effect of *p*H on complex-formation. Succeeding chapters provide much information concerning end point detection, metal indicators, the use of masking agents, the determination of more than thirty metals, indirect methods for anions, and applications to polarography, amperometry, and qualitative analysis. Two chapters are devoted to the determination of calcium and magnesium in water and in a great variety of materials ranging from alloys, cements, and rocks to biological fluids and foods.

The subject-matter is mainly concerned with volumetric applications of ethylenediamine tetraacetic acid, but an interesting final chapter concerns the uses of the reagent to complex interfering ions, and thus facilitate more orthodox analytical work such as the colorimetric determination of bismuth, cobalt, and copper with diethyldithiocarbamate, the determination of mercury with dithizone, the spectrophotometric determination of beryllium in the presence of aluminium, the mannitol–boric acid titration in the presence of iron and other metals, the separation of the rare earths, and the gravimetric determination of uranium in the presence of other metals.

This book will be a very useful guide for the analytical chemist, though, as the treatment is mainly non-critical, many of the methods dealt with will call for some preliminary trials before being accepted for any specific purpose. However, this is in no way a criticism of Prof. Welcher's comprehensive compendium, which will be of the utmost assistance to those interested in the analytical chemistry of ethylenediamine tetraacetic acid. C. O. HARVEY

NOISE

Principles of Noise

By Dr. J. J. Freeman. Pp. x+299. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1958.) 74*s*. net.

DURING the past few years considerable attention has been focused on the problem of detecting ever smaller signals; this requirement has been forced upon us from a number of quarters, prominent among which are radio, astronomy, and electromedicine.

The detection of these small signals is accompanied by the desire for a theory applicable to the random fluctuations with which the signal may be associated. Although investigations into electrical noise date back to Johnson's classical paper in 1928, until recently there have been very few books written in an attempt to integrate knowledge throughout the whole field of noise, and even fewer which have approached it in a tutorial manner designed for a reader with little previous knowledge of the subject. This is the task which the author has set himself.

The preamble to his book consists of two chapters dealing with the fundamental mathematical tools with which to attack noise problems. Starting from the basic notion of Fourier series he leads in a simple manner to the idea of Fourier integral and transform. He also introduces the concept of power spectrum and its relationship to autocorrelation function. The chapter on probability covers the principles of this subject, giving insight into the idea of variate space and leading from the notion of discrete probabilities to that of a continuous probability density.

The main text starts with a definition of random processes. Mention is made of the properties of stationary and ergodic processes, illustrating them by means of suitable examples. In fact, one of the great virtues of the book from the point of view of the student approaching the subject in complete ignorance is the large number and relevance of the illustrative examples.

These principles are applied to the derivation of a number of fundamental circuit aspects of noise; derivations which, perhaps in an over-zealous attempt to be straightforward, become rather laboured. The application to practical electrical devices gives a good insight into the noise behaviour of a number of physical devices, in the process of illustrating the application of the theory. This section is naturally far from exhaustive, and this point might have been better brought out if a wider variety of physical systems had been considered; the only devices mentioned are thermionic valves; no mention is made of noise in transistors or other solid-state devices. The section dealing with measurement of noise is, unfortunately, far too brief to do justice to the topic, but as this is essentially a theoretical book this is not of major importance.

The book develops with further theorems related to noise figures and the calculation of optimum arrangements for minimizing them. The reason for this is fully explained in the following chapter which, in great detail, enunciates the problem of detecting ever smaller signals in the presence of noise, stressing the close connexion between accuracy and time taken for an observation.

The remaining section of the book deals with the theoretical aspects of the characteristic function, leading to an analysis of the detection of alternating signals in the presence of noise by means of a non-linear detecting element.

The reason for the final chapter in the book, dealing with target noise, is seen in the author's personal interest in this field. As a consequence, its irrelevant inclusion in a book dealing primarily with the fundamental theory of noise may be excused.

The book thus well comes up to the author's aim of providing a simple introduction to the techniques of noise calculation. From this point of view it is probably the best book yet available for the student and yet one which will be valuable for reference at a later date.

CONVEX GEOMETRY

Convexity

By Dr. H. G. Eggleston. (Cambridge Tracts in Mathematics and Mathematical Physics.) Pp. viii + 136. (Cambridge: At the University Press, 1958.) 21*s*. net.

Problems in Euclidean Space

Application of Convexity. By Dr. H. G. Eggleston. (The Adams Prize Essay of the University of Cambridge, 1955–6.) (International Series of Monographs on Pure and Applied Mathematics, Vol. 5.) Pp. viii + 165. (London and New York: Pergamon Press, 1957.) 40*s*. net.

THE basic concept of convexity is simple but powerful. For example, given an ordinary function the graph of which is convex, so that any arc is below its chord, if arbitrary positive masses are attached to a finite number of points, the centroid of such masses is obviously above the curve; but this almost trivial observation can be made to yield most of the significant elementary inequalities of analysis, such as the Cauchy–Hölder inequality. Again, a set of points is convex if, when A and B belong to the set, so do all the points of the straight line segment AB. Since many elementary geometrical figures are convex, the question of the relation of convexity to properties of such figures at once arises, leading, for example, to the curious and important notion of curves of constant width.

Dr. H. G. Eggleston's two books are complementary. In the Cambridge Tract, the object is to develop the general theory of convexity, for its own sake, in n-dimensional Euclidean space; in the Pergamon Press volume, which consists of the Adams Prize Essay in the University of Cambridge for 1955–56, convexity is the thread connecting a variety of geometrical problems in Euclidean space of two or three dimensions.

A natural description of a plane convex set would be that it lies wholly on one side of any tangent to its boundary, but this is too restrictive (it would rule out a triangle); more generally and more precisely, through every point on the boundary of a convex set there passes a line which does not intersect the set. This provides a convenient and powerful alternative definition of convexity, once its equivalence to the earlier definition is established. Two other valuable tools are the relation between convex sets and convex functions, and Blaschke's selection theorem, which asserts that an infinite aggregate of closed convex sets in a bounded space must contain a sequence converging to a limit set which is closed, convex and not vacuous. All this basic theory is developed for n-space in the first four chapters of the Cambridge Tract. The fifth chapter concerns Minkowski's definition of surface area (the volume is simply the appropriate Lebesgue measure); this is a somewhat difficult chapter, for the motivation will scarcely be clear to the general reader. The final two chapters deal with typical geometrical problems: isoperimetrical properties and curves of constant width.

The second book is divided into four sections. In the first, convexity is merely a tool for the investigation of results in point-set theory; in the second, Borsuk's conjecture that any set of diameter d in n-space is the union (sum) of $n + 1$ sets each of diameter less than d is proved for 3-space by reducing the problem to one concerning convex sets. The third section deals with problems in which convexity appears as a natural restriction on the class of sets involved, such as the measure of closeness of approximation to a convex set by a convex polygon. Finally, special problems about plane convex sets are considered: sets of constant width, and inequalities connecting a plane convex set and its circumscribing triangles.

Dr. Eggleston's exposition is patient and thorough. But the book is for the specialist rather than for the general mathematical reader. Proofs are inevitably long, because of much complicated detail and some tedious but necessary enumeration of cases. Even the author's craftsmanship cannot always cut clearly through the tangle of detail. But there are many unsolved problems in this field, and the young research worker who has a taste for this type of patient analysis will find Dr. Eggleston's books invaluable, both as an account of the present state of knowledge and as a guide to likely lines of advance.

RADIOACTIVITY DUE TO FISSION PRODUCTS IN BIOLOGICAL MATERIAL

By Prof. W. V. MAYNEORD, W. ANDERSON, R. E. BENTLEY, L. K. BURTON, J. O. CROOKALL and N. G. TROTT

Physics Department, Institute of Cancer Research : Royal Cancer Hospital, London

THE release of artificial radioactive products into the biosphere has raised the problem of determ-ing whether or not the resulting increase in the adioactivity of the environment represents a poten-ial hazard to human beings. In attempting to assess ny possible hazard, the first necessity is to obtain ccurate, detailed information on the nature and mounts of radionuclides, both natural and artificial, ccurring in the environment and the human body. ifficult problems arise in these studies of artificial adionuclides, and elaborate techniques are needed r distinguishing them from naturally occurring adioactive species. In Great Britain admirable vestigations have been made by the United King-om Atomic Energy Authority[1–3]. However, in rder to obtain independent information we have ndertaken studies of beta- and gamma-emitting ssion-product radionuclides in biological materials Table 1), the programme being linked with other vestigations in this Department on natural alpha-mitters[5,6]. We outline below the methods we are sing and our initial results for a series of samples of ows' milk and human milk. By a fortunate coincidence the most detailed part of our cows' milk ampling programme covered the week in which the ccident occurred at the Windscale No. 1 pile, and he results therefore provide an interesting record of he levels of fission products in milk produced at that me in Cardiganshire, Wales.

Estimation by Chemical Separation and Beta-Counting

Several radionuclides may be present in a single iological sample, and the levels of artificial and aturally occurring radioactivity in the sample may e of the same order of magnitude. For this reason, nd to concentrate the activity, a suitable chemical eparation must be made before the sample is assayed by beta-counting. Identification of particular radionuclides should be supported by measurements of half-life, or of maximum beta-energy.

able 1. RECENT DATA (REF. 4) FOR CERTAIN FISSION PRODUCTS

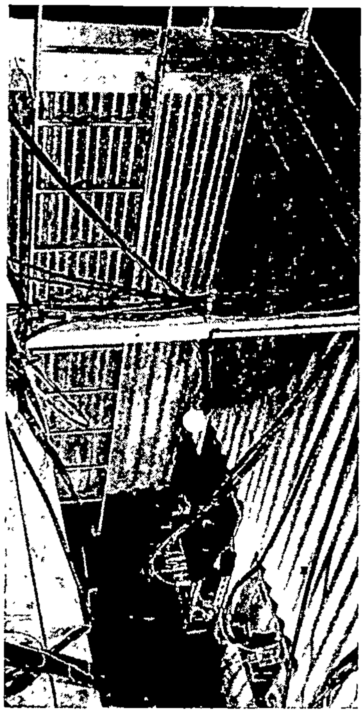

Fig. 1. Low-background pit for sample counting

The activities to be measured are, of course, frequently very small. Preliminary investigations showed that a beta-counting system, with a background of between 0·1 and 1·0 c.p.m. (counts per minute) and an efficiency of approximately 20 per cent, would be suitable for measurements on a wide range of samples. Assemblies were therefore constructed using end-window Geiger–Müller counters (G.E.C. Type *GM*4 *LB*), which have low natural backgrounds. The cosmic-ray background was reduced by the use of an anti-coincidence shield, incorporating 20 glass-wall cosmic-ray counters (20th Century Electronics, Type *G*24). To shield the whole assembly from external gamma-radiation, use was made of the chalk which forms the top rock stratum of our laboratory site, and is low in radioactive content. A pit 8 ft. × 3 ft. × 7 ft. deep, with five short galleries (Fig. 1), was excavated in the rock beneath a basement laboratory. The counter assemblies were set up in these galleries with additional shielding of 2 in. of 50-year-old lead. The background so obtained for a number of sample

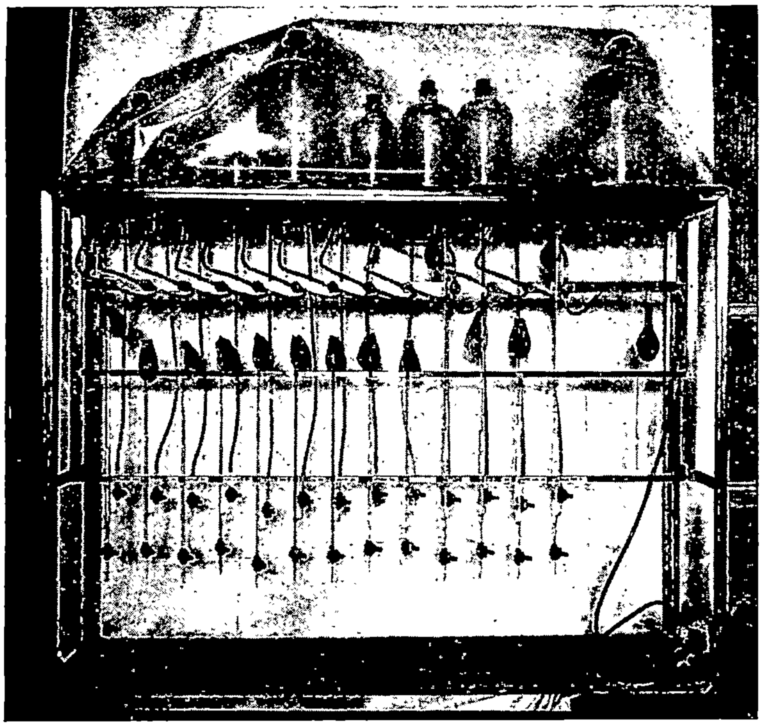

Fig. 2. Dispensing system for isolating chemical reagents from the laboratory atmosphere

counters has ranged from 0·4 to 0·6 c.p.m., individual counters showing variations from the mean not exceeding ± 0·05 c.p.m. over a period of several weeks.

The analysis of samples for radiostrontium involves the use of a number of chemical reagents and separation procedures. To reduce the possibility of obtaining false results due to radioactive contamination, several precautions were taken. Adequate stocks of prepared reagents, isolated from the atmosphere, were stored in a special dispensing system (Fig. 2). Provided that a control sample showed no measurable activity, it could be assumed that none would be introduced by the reagents during the ensuing series of estimations. The laboratories were quite separate from those used for normal radioactive tracer work, and access was strictly limited. We have collected a number of sealed samples of pre-1945 materials, including some of the foodstuffs recently recovered from the Scott/Shackleton stores in Antarctica. These fission-product-free materials have been used in periodic control runs, which have shown the reagents to be free from radioactive contamination at levels we can detect.

The radiochemical procedures used in the estimation of strontium-90 and strontium-89 were basically those described by Bryant *et al.*[7]. Milligram quantities of inactive strontium are added as carrier to ashed samples of biological materials, followed by chemical separation of the strontium from the mixture. Final scavenging with barium chromate and then ferric hydroxide removes trace amounts of natural series radionuclides and rare earth fission products that may be present. A small amount of inactive yttrium as carrier is then added to the strontium fraction and the solution stored for about two weeks while yttrium-90 builds up to nearly complete radioactive equilibrium with the parent strontium-90. Estimations of strontium-90 are based on measurements of the daughter yttrium-90 selectively precipitated as yttrium hydroxide and mounted for counting as oxalate. Estimations of strontium-89 are based on measurements of the strontium fraction precipitated as carbonate allowance being made for strontium-90 and yttrium-90 in the precipitate.

The decay of yttrium-90 and strontium-89 fractions has always been followed. Typical results are shown in Fig. 3. In our experience measured half-lives agreed, within the limits set by counting errors with the known values for these nuclides.

The end-window counters were calibrated individually for each of the nuclides studied. The stock solutions had been standardized in this laboratory (for strontium-90 plus yttrium-90 also at the National Physical Laboratory), by 4π beta-counting[8]. Dilutions, prepared gravimetrically, were treated chemically as described above to prepare sources of known activity for counting. As a further check on the accuracy of the calibrations, measurements were made on an international strontium-90 plus yttrium-90 milk ash standard, distributed by the United States Atomic Energy Commission Health and Safety Laboratory our values were in good agreement with the mean of those of several other laboratories.

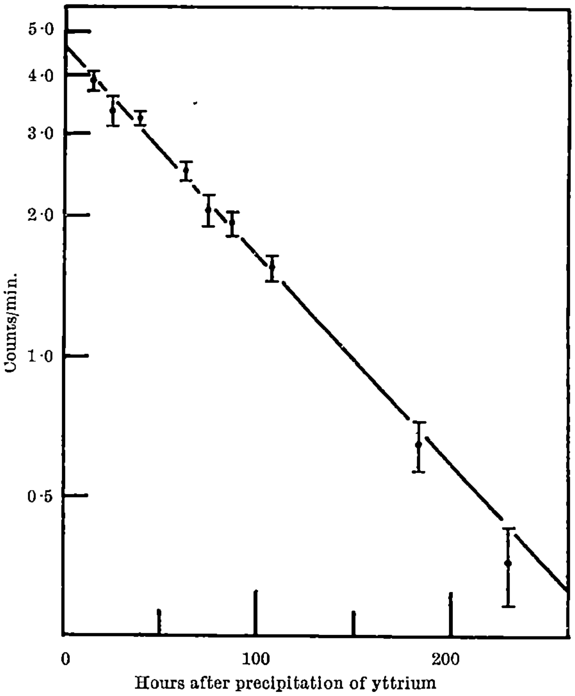

Fig. 3. Typical decay curve for yttrium-90 sample derived from cows' milk (sample *CMF* 1). The errors shown (2 σ) are based on the total number of counts measured for each point corrected for background. The curve is fitted by the method of least squares with due allowance for the weight of each measured value. Measured $T_{1/2}$ = 66·4 hr. (σ = 0·7). (cf. 65 hr., ref. 4)

Estimation by Gamma-Scintillation Spectrometry

In favourable cases gamma-emitting nuclides in biological samples may be identified and assayed by direct measurements using a sodium iodide gamma-scintillation spectrometer. This technique has the further advantage that comparatively large samples may be used, since self-absorption of gamma-radiation is small.

We have used two systems, each of which was carefully calibrated with standard sources prepared in a form simulating the samples to be assayed. In the first system a crystal 4 in. diameter × 2 in. high and photomultiplier, coupled through standard equipment to a single-channel pulse-height analyser, was set up in a gallery of the low background pit. A second, and improved system, was designed to have an inherent low background and high stability. A crystal 3 in. diameter × 3 in. high, with very low natural radioactive content (2–4 parts per million potassium), canned in electrolytic copper and having a quartz window, was used (Harshaw Chemical Co.). The associated photomultiplier has a stainless steel housing, and the whole detector is shielded by 16 in. of steel. The system is operated in conjunction with a 99-channel pulse-height analyser (A.E.R.E. Type 1438*B* and *C*) and has a total background above 100 keV. of 350 c.p.m. The capabilities of our equipment are illustrated by the ability to identify and measure as little as 20 μμc. of cæsium-137 in a human milk sample in measurements over a counting time of 36 hr.

Measurements on Cows' Milk

At the present time, the immediate sources carrying fission products into the human body are not fully known. It is clear, however, that in Great Britain milk is a principal source of strontium-90, the fission product causing greatest concern[9]. We therefore decided to make measurements of strontium-90 in milk in order to establish the average level for a well-defined area and to follow the general trend of levels with time.

Apart from the influence of fall-out rate, variations in the levels of fission products occurring in milk may be caused by numerous factors. For the proposed investigation, it was essential to obtain samples representative of a large quantity of milk so that fluctuations, reflecting special conditions at individual farms, would be smoothed out. By kind co-operation of the Milk Marketing Board we have arranged for a supply of spray-dried, skimmed-milk samples to be sent to us at weekly intervals from Felinfach Creamery, where up to 30,000 gallons of milk, drawn from more than 1,500 farms, are processed daily. The farms are located in an area of mixed coastal and upland herbage covering a few hundred square miles in west Cardiganshire. Each sample is a composite one, prepared from periodic samplings of the dried product made at half-hourly intervals throughout a given day. Four consecutive weekly samples are eventually bulked together, and it is proposed to measure the levels of strontium-90 in these bulked preparations over an extended period. In addition, the levels of other fission products, particularly strontium-89 and cæsium-137, are being followed.

As a preliminary investigation, in order to obtain information on the variations which might occur over short times, a series of daily samples was obtained covering October 5–13, 1957. During this period radioactive material was released into the atmosphere as a result of the accident at the Windscale No. 1 pile (October 10 and 11)[10]. Numerous measurements were made on the levels of activity in these daily samples and afterwards in samples produced at fortnightly intervals until December 1957, when the bulked series was commenced. The results of these measurements are shown in Fig. 4. In addition to the results shown in Fig. 4, measurements were made on three samples produced at the same creamery during 1956–57 (Table 2,*a*). The principal effects of the Windscale accident, discussed below, were temporary increases in the iodine-131 and cæsium-137 levels; no effect on the radiostrontium-levels was detected. The main features of the results for each nuclide studied are as follows:

Strontium-90. The main information on the levels of strontium-90 occurring in milk produced in Great Britain is that published by Bryant *et al.*[1,2]. The annual mean values found by these workers for a series of samples produced in Somerset during 1955 and 1956 were respectively 4·0 and 4·5 S.U. (1 S.U. = 1 μμc. ^{90}Sr/gm. calcium). Recently, they have reported a value of 5·1 S.U. (median) for 1957 for the same series[11]. Further measurements on samples produced during October and December 1956 at five other locations in Britain gave values ranging from 3·9 to 10·3 S.U., indicating a regional variation. Such variations have been discussed recently in terms of climatic and soil conditions[12].

The results obtained by us for Cardiganshire during 1956–57 are in close agreement with those of Bryant *et al.* for the same region and period (Table 2,*a*). Our later results, extending from October 1957 to May 1958 (mean value = 8·3 S.U.), show little change

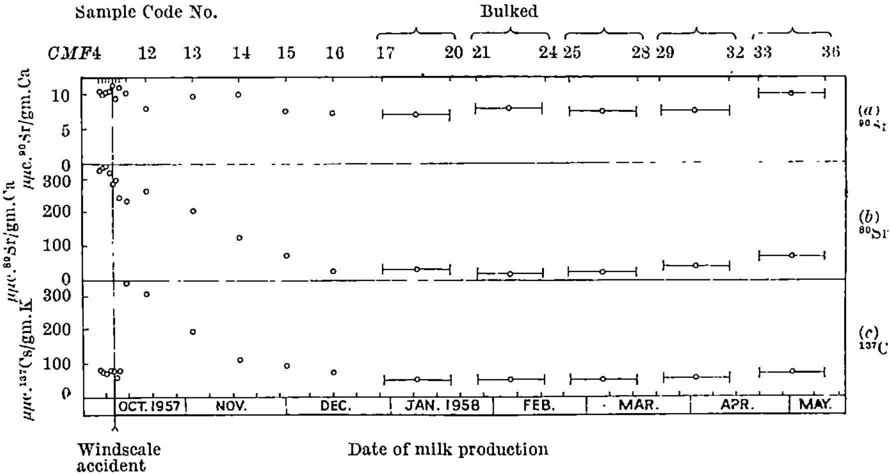

Fig. 4. Levels of fission products in cows' milk from west Cardiganshire, Wales, October 1957 to May 1958. All the values shown are accurate to within ± 10 per cent

Table 2. (*a*) STRONTIUM-90 AND CÆSIUM-137 LEVELS FOR PRE-OCTOBER 1957 SAMPLES OF COWS' MILK (WALES)

CMF 12	19/10/57	32×10^3	32×10^2

Column 3 directly estimated from measurements; column 4 derived from column 3 assuming no loss in drying and same specific activity in whole and skimmed milk.

from the earlier values. Looking at Fig. 4,*a* it will be seen that neither during the week covering the Windscale accident, nor afterwards, was there any demonstrable increase in the strontium-90 content of the milk examined. The mean of the levels shown for October and November 1957 is 10·2 S.U., being slightly higher than the mean level of 7·6 S.U. for the subsequent months until April 1958. The value for May 1958 is again higher, 10·1 S.U., indicating a seasonal variation.

It will be seen that the levels found for strontium-90 in milk over the period 1955–58 have remained surprisingly steady. This suggests that the levels are not building up proportionately to the cumulative fall-out.

Strontium-89. The values for strontium-89 (Fig. 4,*b*) fall progressively from October 1957 until January 1958, the strontium-89/strontium-90 ratio decreasing from 30 to 4 over this period. Similar effects were found by Bryant *et al.*[1] in samples produced in October and December 1956, and, as suggested by these workers, the results may be due to a change-over from fresh grass to stored fodder depleted in strontium-89 by natural decay (half-life = 54 days).

It appears from the present series that the average strontium-89/strontium-90 ratio during October 1957 was above 20. This figure may be compared with the average monthly ratios found by Stewart *et al.*[13] in rainwater at Milford Haven over the period May 1954–May 1957. These values range from less than 1 to a maximum of 45. On the other hand, owing to the short half-life of strontium-89, the strontium-89/strontium-90 ratio computed for the total fall-out accumulated on the ground has never exceeded a value of 2. Our average monthly ratio exceeding 20 in milk indicates that a significant fraction of the strontium-90 in milk is derived from fall-out of fairly recent origin. This result is in keeping with the view that the levels of strontium-90 in milk depend on the rate of fall-out and do not rise in proportion to the cumulative fall-out.

Cæsium-137. The levels of cæsium-137, both i samples produced immediately before the Windscal accident and after December 1957, are close to thos found in our three 1956 samples (Table 2,*a*). Simila values were obtained by Booker[3] for Welsh mill sampled in October 1956. Excluding the rise immediately after the Windscale accident these results follow the pattern for strontium-90, namely, that the level due to fall-out have remained steady. It is interesting to note that, as for strontium-90, the levels of cæsium 137 in the present Cardiganshire series are approximately double those reported for Somerset during 1955–56 [3].

Effect of the Windscale accident on the levels o cæsium-137 *and iodine*-131. The area from which th present series of samples is drawn is approximatel 160 miles south-south-west of Windscale. At th time of the accident our arrangements for gamma scintillation spectrometry were incomplete, but w were able to set up rapidly the single-channel system described above and to carry out measurements directly on dried milk samples (0·5–1 kgm.) a few days after the accident. This system was used for measuring the levels of iodine-131 in three samples produced shortly after the accident. This radionuclide was identified by observation of a peak appearing at 360 keV. combined with estimations of half-life. The results of these measurements are listed in Table 2,*b*. It will be seen that, although the cloud avoided north Wales[14], in south Wales some deposition occurred. Further measurements with the single-channel system demonstrated in samples produced immediately after the Windscale event a pronounced rise in gamma-activity in the 600–700 keV. band. It was not possible for us to analyse this activity in detail, but the evidence to hand suggests that about one-half of the activity was due to short-lived gamma-emitters, the observed 'half-life' being in the region of 2 months. (This activity is probably to be ascribed to zirconium-95 and niobium-95 [16].) The remainder of the activity was due to cæsium-137, identification being made by precise measurements using the 99-channel analyser system when the samples were at least nine months old. The values shown in Table 2,*a* and Fig. 4,*c* obtained on this system are based on spectral curves as illustrated in Fig. 5,*b*.

Our results illustrate the transient nature of the increase, due to the accident, of the activity occurring in milk. This is particularly well shown for cæsium-137, where the levels had returned to pre-accident values some two months afterwards. The progressive decrease in levels (Fig. 4) is similar to that found for strontium-89 over the same period and may be related partly to the change-over in the cows' feed during winter. It is noteworthy that the cæsium-137 level

Table 3. STRONTIUM-90, STRONTIUM-89 AND CÆSIUM-137 IN SAMPLES OF HUMAN MILK

Sample	Date collected	$\mu\mu$c. Strontium-90		$\mu\mu$c. Strontium-89		$\mu\mu$c. Cæsium-137		
		Per gm. Ca in ash (*a*)	Per litre liquid milk	Per gm. Ca in ash (*a*)	Per litre liquid milk	Per gm. ash (*b*)	Per gm. K in ash (*a*)	Per litre liquid milk

HM 4	Oct. 12–20, 1957	—	—	—	—	4·9	20	9·4

(*a*) Calcium and potassium content measured for individual samples; (*b*) in our experience, less than 20 per cent of the total cæsium-137 present in milk is lost during ashing at 600° C.

for May 1958, although showing a slight rise above the winter values, is still close to the pre-accident level. This indicates that the activity released during the accident is no longer being incorporated in the grass.

The ratio of iodine-131 to cæsium-137 in our sample produced on October 13, 1957, was 20, lying between values reported for airborne activity on October 11 by Stewart *et al.*[14] (9·0) and Chamberlain *et al.*[15] (38·5). The increases in absolute levels in Cardiganshire were considerably smaller than those reported at Windscale. Thus, the iodine-131 value found by us on October 13 was less than 1 per cent of the highest level (1·4 μc./litre) found in the Windscale area (October 13, at a farm 10 miles from the works)[16]. There is little doubt, however, that the increases measured for Cardiganshire were a result of the accident and not a result of fall-out from distant bomb tests, which would have produced a corresponding increase in radiostrontium-levels.

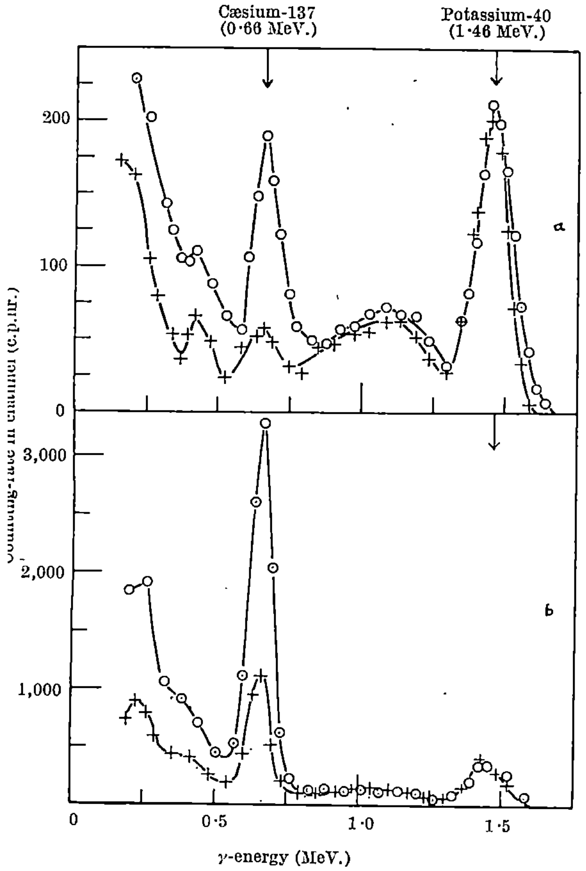

Fig. 5. Typical gamma-spectra of milk samples, determined in July 1958, using 99 channel analyser and low background (NaI(Tl)) crystal assembly.
(*a*) (i) Ashed cows' milk *OM* 8 15·5 gm. (pre-1945) (+); (ii) ashed human milk *HM* 3 13·3 gm. collected October 1957) (○). (*b*) (i) Dried cows' milk *CMF* 4 451 gm. Measurements on Human Milk

We have made observations upon four samples of human milk, ranging in volume from 2·5 to 6 litres. Each sample was obtained from an individual donor and was collected over a period of a few weeks during September and November 1957. On receipt the milk was reduced to dryness and then to ash. Gamma-spectra were obtained for these ashed samples using the multichannel analyser, and in each case the photopeak of cæsium-137 was found at 660 keV. A typical spectrum is shown in Fig. 5,*a*, in comparison with a spectrum obtained from a pre-1945 sample of cows' milk ash. Estimated activities in the samples are given in Table 3. Two of the samples were analysed for radiostrontium but it was not possible to detect any such activity. The values for strontium-90 and strontium-89 shown in Table 3 are upper limits based on the limiting sensitivity of the method.

We are not aware of previous measurements of cæsium-137 in human milk. The levels we have found (expressed as μμc./gm. potassium) are similar to those observed in cows' milk from Somerset[3] and about one-third of the values in our Cardiganshire series. It is interesting to note that these levels in human milk are very close to those reported by Rundo (20–48 μμc./gm. potassium)[17] for total body measurements on human subjects during 1956–57.

In summary, it will be seen that our measurements of the levels of activity of fission products in milk are, where comparable, in good agreement with those previously published. It was possible to detect a small transient increase of iodine-131 and cæsium-137 levels in south Wales following the Windscale accident. It appears, however, that over three years the level of strontium-90 has remained fairly steady. Small changes have occurred but those which have so far been observed are unlikely to be biologically significant.

These investigations are being continued and extended to include other, short-lived, radionuclides and a wider range of biological materials. Throughout, attention is being directed to a comparative study of the levels of artificial and naturally occurring radionuclides.

We wish to thank Dr. A. L. Provan of the Milk Marketing Board for his collaboration in our sampling programmes. Thanks are also due to Mr. W. Binks, director, Radiological Protection Service, for permission to use a multi-channel analyser.

Valuable assistance was given by Mr. H. J. D. Ireland in the development of the counting equipment, and by Miss A. Dulley and Mr. D. Smith in the estimations.

The investigations were supported by grants from the Medical Research Council.

THE LOCAL SUPERCLUSTER OF GALAXIES

By GERARD de VAUCOULEURS

Harvard College Observatory, Cambridge, Massachusetts

IN 1946, G. Gamow[1] advanced the speculative hypothesis that, possibly, " . . . the realm of galaxies . . . represents only a small part of a much larger system (a 'super-galaxy' in the super-Shapley sense) rotating around a distant centre", perhaps " . . . located far beyond the reach of our telescopes". As a test of this hypothesis, he suggested a search for a double-sine periodicity, similar to the Oort effect of stellar radial velocities in the Galaxy, in the radial velocities of external galaxies.

In 1951, Mrs. V. Cooper-Rubin[2] analysed the available velocities of about one hundred galaxies and found evidence for such an effect; the expected alternation of positive and negative residual velocities (after correction for solar motion and a linear red shift) was best displayed along a great circle of the sphere the pole of which was located at galactic co-ordinates $l = 14°$, $b = +10°$. This was taken to define a 'universal' plane of rotation, and tentative rotational constants were derived for the 'universe'. The direction of the centre was placed near $l = 104°$, $b = +5°$ or 180° from this position.

In 1952, K. F. Ogorodnikov[3] carried out a similar analysis with widely different results: the pole was located near $l = 110°$, $b = 0°$, and the direction of the centre was near $l = 20°$, $b = +88°$. It now appears that these early studies were confused by the use of a first-order theory based on the arbitrary assumption that the rotating super-system of galaxies must be identical with the whole 'universe' or 'metagalaxy'.

In 1953, I pointed out[4] (as others[5,6] had done before) the apparent concentration of galaxies brighter than about 15th magnitude towards and along a great circle of the sphere the pole of which was placed at $l = 15°$, $b = +5°$ (Fig. 1). Earlier statistical studies[7,8] had

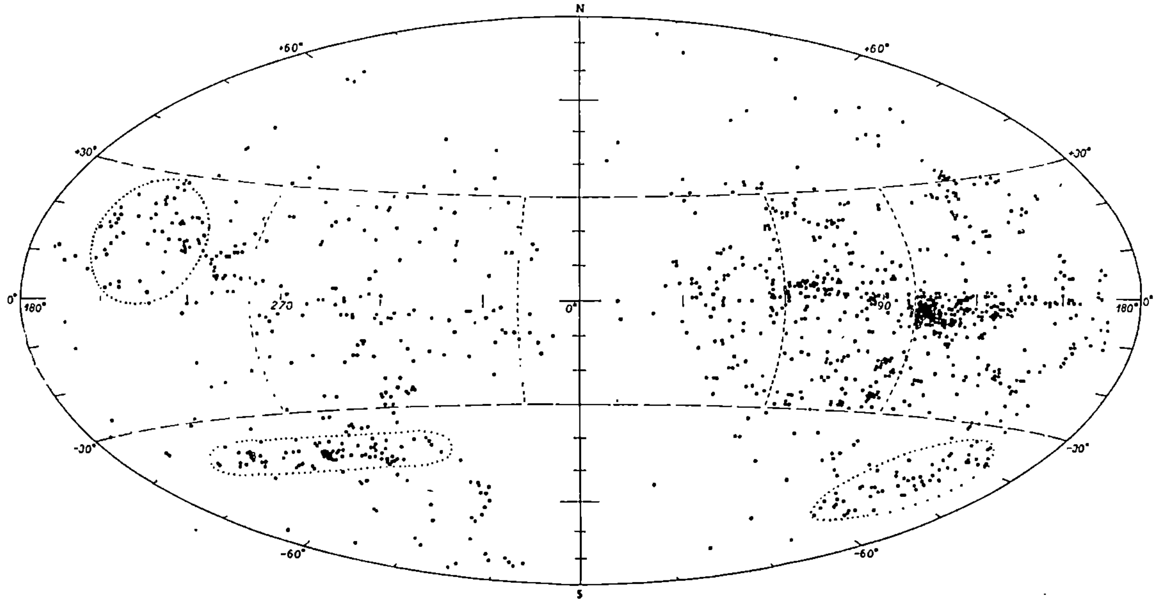

Fig. 1. Distribution in supergalactic co-ordinates of the brighter galaxies ($8{\cdot}0 \leq m_{pg} \leq 12{\cdot}9$). The northern galactic hemisphere is to the right; galaxies of known velocity are denoted by filled circles; those of unknown velocity, by open circles. Note that the majority of the galaxies lie between latitudes ± 30°. Three probable external supersystems are outlined by dots. The two critical longitude sectors discussed in the text are delimited by short dashes

indicated the presence of a large 'metagalactic' cluster or supercluster in our neighbourhood with a centre in the general direction of the north galactic pole, but they had received little attention. I therefore suggested that this 'Milky Way' of galaxies is the trace of a local super-system of clouds and clusters of galaxies—a local Supergalaxy—within which the local group of galaxies (including our own) is located, rather far away from a centre placed in or near the great Virgo cluster of galaxies at $l = 255°$, $b = +75°$.

Further study[9] indicated an overall diameter of 6–8 megaparsecs on the old (1936) distance scale, corresponding to about 30 megaparsecs on the current scale. The distance of the Virgo cluster is 10–13 megaparsecs in this revised scale.

The strong flattening of the system (axial ratio 1 to 5) was from the beginning[4,9] taken as supporting evidence for the hypothesis of a general rotation. Rotation, in fact, constitutes the critical test of the reality of the super-system as a physical unit held together by its self-gravitation; for in the absence of rotation the singular distribution of the nearer galaxies would have to be regarded as not significant, merely a chance grouping of a number of independent clouds and clusters.

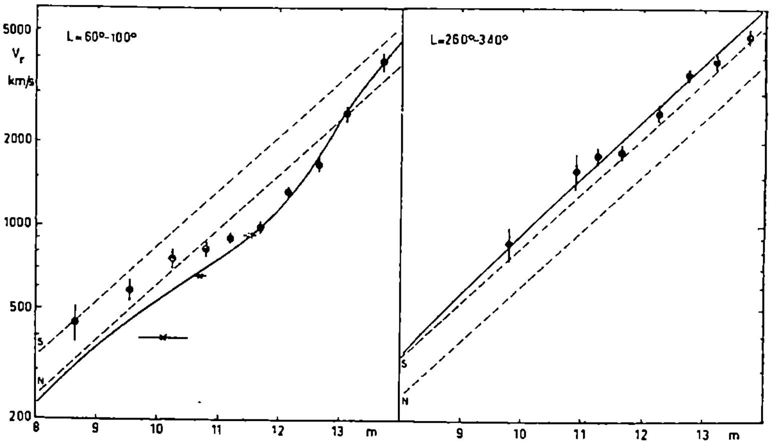

Fig. 3. Mean radial velocities of galaxies in the supergalactic equatorial belt as a function of magnitude in two longitude sectors. The theoretical curves are computed from the model described in the text. The dashed lines are the solutions for uniform expansion in the northern and the southern galactic hemispheres, according to Sandage. The crosses (left) give the mean magnitude $\bar{m}(V_r)$ in three velocity ranges to illustrate regression effects

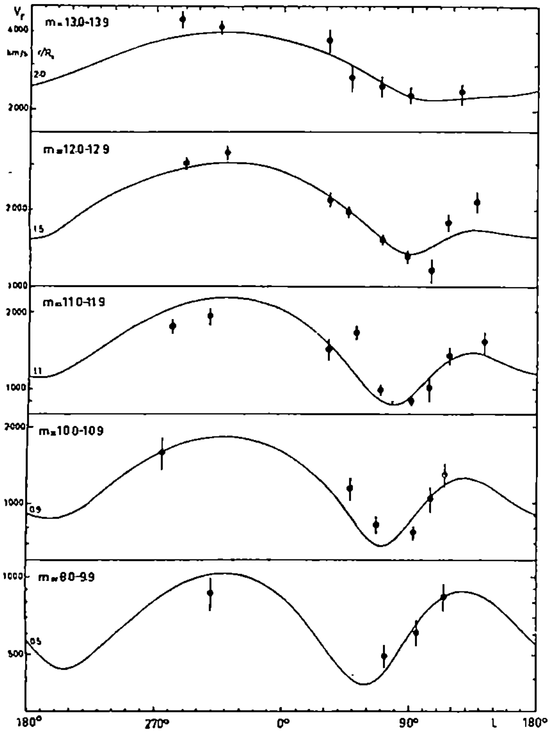

Fig. 2. Mean radial velocities of galaxies brighter than the 14th magnitude as a function of supergalactic longitude. The mean points with their probable errors refer to more than 300 galaxies within ± 30° of the supergalactic equator. The theoretical curves are computed from the model described in the text

A critical check has become possible through the publication in 1956 of the Lick – Mt. Wilson – Palomar general catalogue of radial velocities of galaxies[10]. Fig. 2 and Fig. 3 show the main results of an analysis of the radial velocities of more than 300 galaxies brighter than the 14th magnitude and located within 30° of the supergalactic equator.

In Fig. 2 the mean radial velocities are plotted as a function of supergalactic longitude L for 5 intervals of apparent magnitude. The mean points disclose a conspicuous, systematic longitude effect which, at small distances (small m), approximates the double-sine wave expected in a system in differential rotation.

In Fig. 3 the mean radial velocities are plotted against apparent magnitude for two critical longitude sectors. In the sector $260° \leqslant L \leqslant 340°$, corresponding to the supergalactic anti-centre sector (and to the southern galactic hemisphere), the relation between $\log V_r$ and m is approximately linear; in the other sector, $60° \leqslant L \leqslant 100°$ (near the north galactic pole), the non-linearity is conspicuous; further, the mean velocities at a given apparent magnitude (hence, at a given distance) are widely different in the two sectors.

This discrepancy had already been noted by Sandage[10] as a puzzling effect detracting from the usual assumption of isotropy. The conclusion seems inevitable that, contrary to orthodox theory, the red shift is neither linear nor isotropic among the brighter galaxies; the results are, however, consistent with and easily interpreted by the Supergalaxy hypothesis.

We assume that the local supercluster is in a state of differential rotation and differential expansion about its centre in the Virgo cluster. The first assumption does not require amplification; the second, which accounts for the north-south asymmetry, is made the more plausible by a variety of theoretical and empirical arguments suggesting that in condensed regions of space (groups, clusters) the expansion rate is reduced locally by gravitational attraction; for example, the Galaxy and the local group are probably not expanding. On these assumptions, the radial velocity of a galaxy in longitude L at distance r from us, and R from the centre of rotation, is given by the classical relation:

$$V_r = R_1[\omega(R) - \omega_1]\sin(L - L_0) - R_1[\varepsilon(R) - \varepsilon_1]\cos(L - L_0) + \varepsilon(R)\cdot r \qquad (1)$$

For the purpose of computing a simple model it is assumed that the angular velocity, $\omega(R)$, and the expansion-rate, $\varepsilon(R) = R'/R$, are of the forms:

$$\omega(R) = \omega_0 \exp(-R/R_1)^2 \qquad (2)$$

$$\varepsilon(R) = \varepsilon_\infty[1 - \exp(-R/R_1)] \qquad (3)$$

if R_1 is the distance of the Galaxy to the centre in longitude L_0.

Note that the only free parameter for adjustment to the observations is the rotational velocity, $R_1\omega_1 = R_1\omega(R_1)$, of the Galaxy, since all others are determined uniquely in our hypothesis by the longitude, $L_0 = 104°$, and the radial velocity, $\varepsilon_1 R_1 = +1{,}100$ km./sec., of the Virgo cluster. Further, the auxiliary relation between apparent magnitude m and distance r is also given by the Virgo cluster where $\overline{m} = 11 \cdot 5$ at $r = R_1$.

As shown by the computed curves in Figs. 2 and 3, excellent agreement is obtained if $\omega_1 R_1 = 500$ km./sec. (with an estimated probable error of ± 50 km./sec. The values of r/R_1 range from 0·5 to 2·0 as m increases from 8–9 to 13–14; this large range makes it clear why a first-order theory is inapplicable, quite apart from the complication of the non-linear expansion.

From the rotational velocity we derive the total mass of the supersystem, $M(\text{tot.}) \approx 10^{15}$ solar masses (assuming a modulus $m_0 - M = 30 \cdot 0$, $R_1 = 10$ Mpc.). This appears to be a reasonable value when compared with estimates of the mass of the Virgo cluster, $M(\text{nucleus}) \approx 10^{14}$ solar masses, based on velocity dispersion[16].

This analysis supports the conclusion that the local supercluster of galaxies is an irregular assembly of groups, clouds and clusters dominated by the Virgo cluster in its centre, and that it has reached at least some degree of dynamical equilibrium involving rotation, expansion, and random motions. The Galaxy partakes in the slow general rotation of the system with a velocity of the order of 500 km./sec. directed towards $L = 194°$ ($l = 287°$, $b = -14°$). The present or 'instantaneous' period of revolution is of the order of 5×10^{10} years near the centre, and from 10 to 20×10^{10} years in the outer regions.

The presence of differential expansion in the local super-system has an important consequence for the calibration of the law of red shifts, namely, the derivation of Hubble's expansion parameter, $H = V_r/r$. This is customarily done simply by dividing the velocity by the distance of the Virgo cluster, because it is the only one with both a significant red-shift and a distance small enough to be within the range of comparatively reliable distance indicators; with present 'best' estimates[12], $V_r = +1{,}136$ km./sec., and $m - M = 30 \cdot 7$, $H = 83$ km./sec. per Mpc. However, from equation (3), it follows that the apparent recession-rate of the Virgo cluster is $\varepsilon_1 < \varepsilon_\infty = H$. In the model above, $\varepsilon_1 = 0 \cdot 632\varepsilon_\infty$, so that if $R_1\varepsilon_1 = 1{,}100$ km./sec. and $R_1 = 10$ Mpc., $\varepsilon_\infty = 174$ km./sec. per Mpc.; if $R_1\varepsilon_1 = 1{,}136$ km./sec. and $R_1 = 12 \cdot 6$ Mpc. (modulus 30·7 less 0·2 mag. local absorption correction), $\varepsilon_\infty = \mathrm{H} \approx 140$ km./sec. per Mpc.

Another consequence of differential rotation and expansion is that, in deriving the mean absolute magnitudes of galaxies from residuals of the velocity – magnitude relation, it is necessary to take account of the non-linearity and anisotropy of the velocity field. Details will be published shortly in the *Astronomical Journal*.

Although the philosophical notion of second-order clustering is an old one[13], the general existence of super-clusters of galaxies has only recently been demonstrated (and it is not yet universally accepted), mainly through the statistical analysis of counts of faint galaxies at Lick[14,15] and of clusters of galaxies at Palomar[16]. G. Abell[17] has recently reported preliminary estimates of the average size of some distant super-clusters which (on the same distance scale) agree well with the estimated diameter of the local supercluster.

MIOCENE MAMMALIA FROM THE NAPAK VOLCANICS, KARAMOJA, UGANDA

By DR. W. W. BISHOP

Geological Survey of Uganda

THE mountain mass of Napak in Karamoja District, north-east Uganda (2° 5′ N., 34° 17′ E.) is the dissected remnant of a Tertiary volcanic cone in the group that includes Elgon, Kadam, Moroto and Toror (Fig. 1).

Mammalia were recorded from Napak as early as 1920 by E. J. Wayland but were not identifiable[1]. In 1957, eight fossils were forwarded to the Geological Survey by J. G. Wilson, an officer of the Agricultural Department. Dr. A. F. Trendall of the Geological Survey reported that detailed work might prove rewarding and as Wilson's specimens included a shattered proboscidean molar and a well-preserved rodent skull I went to the area early in 1958.

Fig. 2. Molars and tusk of *Trilophodon angustidens*

Three fossiliferous localities have been located but only the main site is described here. This is situated at a radial distance of six miles south-west of the carbonatite and ijolite plug which marks the position of the central vent. The fossiliferous beds are a series 100 ft. in thickness of horizontally bedded, unconsolidated fine grey tuffs with occasional agglomerate bands. The beds overlie a lava and thick coarse agglomerate and are in turn overlain by further agglomerate. The base of the fossiliferous series occurs at a height of 4,480 ft. O.D. and is 500 ft. above the basement rocks at this point. The beds are of only limited extent and owe their origin to the existence of a subsidiary vent, now represented by an agglomerate plug, which blocked a shallow valley on the flanks of the main volcano. Into the hollow so formed, fine detritus was washed, and ash and agglomerate were deposited by minor outbursts of activity. The hollow may have held water for short periods after heavy rainfall.

Local non-sequences and reddened surfaces, the occurrence of abundant fossil wood and the presence of layers of calcareous nodules (kunkar), flags with rain-spotting, and layers of curled, sun-dried mudstone, give evidence of numerous breaks in deposition. The fossils occur sparingly upon these temporary land surfaces.

Fig. 1. Distribution of fossiliferous Lower Miocene deposits and the genus *Proconsul*. 1, Karungu; 2, Mfwangano; 3, Rusinga; 4, Uyoma; 5, Homa; 6, Maboko; 7, Majiwa; 8, Mariwa; 9, Ombo; 10, Songhor; 11, Muhoroni; 12, Koru; 13, Suk escarpment; 14, Loperot; 15, Losodok; 16, Napak; *E*, Elgon; *K*, Kadam; *N*, Napak; *M*, Moroto; *T*, Toror

To date the site has yielded 1,114 mammalian fossils. Of these, 778 are unidentifiable fragments of bone and tusk, many of which show marks of the teeth of carnivores. The remaining 336 pieces are made up as follows: 39 fragments of proboscidean teeth, including four well-preserved molars, and 45 fragments of tusk (Fig. 2); 35 pieces of rodent skull, jaw and teeth; 29 fragments of skull, jaw and teeth of various Primates, Carnivora, Artiodactyla and Perissodactyla; and 188 bones with distinct facets or form which are probably identifiable.

From a preliminary examination the following mammalia have been tentatively listed as occurring; *Proconsul nyanzae* (Le Gros Clark and Leakey); *Limnopithecus* sp.; Lemuroidea; Histricomorpha; Pedetidae; Anomaluroidea; *Pterodon* sp.; *Amphicyon* sp.; Carnivora; Suidae; Tragulidae; Chalicotheriidae; *Trilophodon angustidens* var. *kisumuensis* (Macinnes); Gastropoda (indet.); abundant fossil wood and occasional leaf impressions.

I am indebted to Mrs. S. Coryndon and to my wife for help with identification, and to Dr. L. S. B. Leakey, curator of the Coryndon Museum, Nairobi, for permission to study comparative material from Kenya and for the following note.

"I have made a preliminary examination of the better preserved fossils found by Dr. Bishop and they are of exceptional interest. Although the collection is small it includes enough typical forms to leave no doubt as to its affinities with the Lower Miocene faunas from Rusinga, Mfwangano, Songhor, Koru and the Lake Rudolf areas of Kenya.

"Of special interest is the presence of *Proconsul nyanzae* and the genus *Limnopithecus*. The former is represented by a very beautifully preserved and quite typical lower right second molar (Fig. 3) while the latter is part of the mandible in which the preservation is less good. There is no doubt that it represents the genus *Limnopithecus* and is probably referable to the species *legetet* but without a better specimen this cannot be stated with certainty."

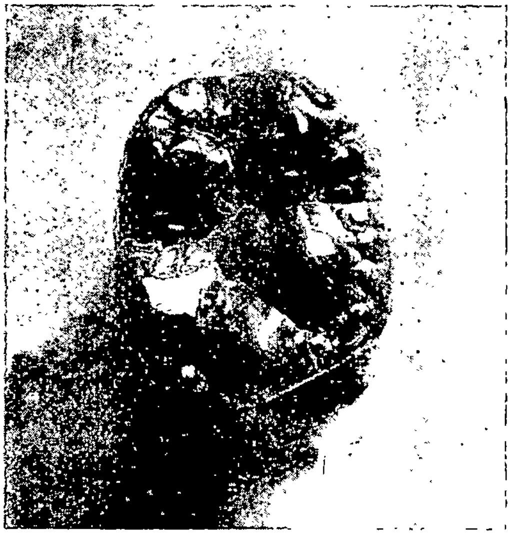

Fig. 3. Lower right second molar of *Proconsul nyanzae*. Maximum length, 12 mm.; maximum width, 10 mm.; posterior edge of tooth at bottom of photograph. Photograph: L. S. B. Leakey

The quantitative analysis of the fauna reveals several points of interest. The action of carnivores as scavengers is seen in the numerous chewed bones and also in that 13 per cent of the fragments surviving as fossils are comparatively inedible teeth and jaws. The specimens are invariably broken or chewed before incorporation in the tuff and are never found as associated skeletons. This suggests that the animals died from natural causes or as a result of the action of predators and were not overcome by gases or ejected material during active periods of the volcano.

The most abundant group numerically were the Rodentia, which account for 23 per cent of all the teeth, jaws and skull fragments recovered. An abundance of rodents is also characteristic of the Kenya Lower Miocene.

The occurrence of fossil wood confirms that the non-sequences in the tuff represent periods when the lower slopes of the volcano became clothed temporarily with vegetation and provided a suitable habitat for the Hominoidea, Lemuroidea and Anomaluroidea.

The genus *Proconsul* is now known from ten major localities in western Kenya but this is the first record from Uganda. The distribution of the main localities yielding *Proconsul* together with the principal outcrops of fossiliferous Lower Miocene deposits is shown in Fig. 1.

The Napak material has been submitted to specialists for specific identification, and a full account of the fauna, stratigraphy and geomorphology of the site will be published at a later date. However, there seems little doubt of the similarity between the assemblage and the extensive faunas obtained from the numerous sites in the Kavirondo area of Kenya, 145–170 miles south of Napak. This material, with certain reservations, is at present considered to be of Lower Miocene Age and is equated with the European Burdigalian[2].

The Napak fossils occur in a simple stratigraphical context in a single volcano resting upon extensive peneplained surfaces developed upon steeply dipping Basement Complex rocks. Thus the deposits have a geomorphological importance in their relationship to former erosion-levels which is absent in the Kenya deposits, where large-scale rift movements and local faulting have frequently disturbed the Lower Miocene deposits and obscured their relationship to pre-volcanic surfaces. The importance of the faunal dating of the volcanics is threefold:

1. It establishes a Lower Miocene age for the early activity at Napak and possibly also at the associated volcanoes of Toror, Moroto, Kadam and Elgon. Despite their varying degrees of erosion these have previously been considered as broadly contemporary with Napak and of Pliocene age[3,4].
2. It provides an approximate morphological time-scale for the building up of the predominantly ash and agglomerate cone to about 10,000 feet above the Basement Complex[3], and its subsequent erosion to the present series of isolated hill remnants.
3. It dates the sub-volcanic surfaces of Napak and probably also those beneath Toror, Moroto, Kadam and Elgon as of Pre-Miocene age. It is possible that the more advanced erosion of Napak and Toror may indicate a rather earlier origin than Elgon, Moroto and Kadam. However, I agree with Trendall[5] that it is more likely that the degree of dissection is related to differences in original bulk of the volcanoes and their position in relation to the base-level of erosion and to major watersheds. Their approximate contemporaneity is supported by the similarity in height and form of the basement surfaces beneath Napak, with those of Moroto, Kadam and Elgon. Two major erosion-levels appear to be represented:

(*a*) An upper surface with the following average heights: Moroto 4,900 ft.; Napak 4,900 ft., Kadam 4,900–5,000 ft., Elgon 5,400–6,000 ft.[5-7], which appears to be the equivalent of the Pre-Miocene, Mid-Tertiary, Mid-Miocene, Buganda, Uganda, Middle or Main peneplain of various authors. This level was already being dissected, at the time of commencement of the eruptions, by a lower surface developing at the expense of the upper one and separated from it by an escarpment of almost 1,000 ft.

(*b*) This lower surface occurs at the following average heights: Napak 3,800–4,100 ft., Kadam 3,900–4,100 ft., Elgon 3,500–3,700 ft.[4,5]. This 'Kyoga Surface' of Trendall appears to differ little in height and morphological relationships from the 'End Tertiary' surface of various authors. In eastern Uganda it has been little modified by the formation of the present-day 'Karamoja Plain', which descends gradually towards the south-west from heights of 3,900 ft. at Napak and Kadam and 3,600 ft. north of Elgon[4,6]. This surface has in its turn been only slightly incised by the present drainage, which flows to the local base-level of the Lake Kyoga system at 3,400 ft. O.D.

The lower surface may not be the true time equivalent of the 'End Tertiary' surface elsewhere but the fauna of Napak necessitates at least a local re-dating of the Buganda and Kyoga surfaces as being considerably Pre-Miocene, and slightly Pre-Miocene, respectively. The lack of downcutting into the Kyoga surface in post-Miocene time is remarkable and may well be related to the warping which initiated the Victoria-Kyoga lake system as an extensive 'local' base-level.

This article has been submitted for publication by permission of the Director of the Geological Survey of Uganda.

OBITUARIES

Prof. James Ritchie, C.B.E.

Born in 1882 at Port Elphinstone, Aberdeenshire, the son of the local schoolmaster, James Ritchie, emeritus professor of natural history in the University of Edinburgh and president of the Royal Society of Edinburgh, died suddenly in Edinburgh on October 19 at the age of seventy-six. He had a notable career. Educated at Gordon's College and then at the University of Aberdeen, he joined the staff of the Natural History Department of the Royal Scottish Museum in 1907. Assistant keeper in 1919, he succeeded Dr. Eagle Clarke as keeper of the Department in 1921, but nine years later was appointed to the regius chair of natural history in the University of Aberdeen, following Sir J. Arthur Thomson, under whom he had been trained. In 1936 he returned to Edinburgh as professor of natural history, retiring in 1952. He was elected president of the Royal Society of Edinburgh in 1954.

It was highly fitting that the posts James Ritchie occupied were all designated, as largely remains the custom in Scotland, 'natural history'. He was, above all else, a naturalist, and no one had a better knowledge of the fauna of his country, both in the present and in the past, and more concern for its future. He published extensively and over an exceptionally wide field, ranging from marine hydroids and polyzoans to birds and mammals, and also made notable contributions to archæology, an interest he gained from his father, an earlier James Ritchie and a well-known amateur archæologist. He wrote three books, "The Influence of Man on Animal Life in Scotland" (1920), "Beasts and Birds as Farm Pests" (1931) and "Design in Nature" (1937).

The first of these represents his major contribution—and it is a great one—to knowledge of animal life in Scotland. It may be described as a work of scholarship written by a born naturalist. Ritchie had the advantage, which he stressed, of dealing with a small country and with the changes in the purely post-glacial fauna which neolithic man found when, some 9,000 years ago, he followed the northward migration of these animals into Scotland. He had the further advantage of the recorded observations of many generations of Scottish naturalists, of whom he was the worthy successor and ideal interpreter. This book had great influence on the growth of the youthful science of animal ecology, with its applications in conservation. It won international recognition for its author, including an award of a silver medal by the Société Nationale d'Acclimatation de France.

His investigations and advice were largely responsible for measures of protection for both seals and birds in Scotland. He found, by examination of the contents of caves near Inchnadamph in Sutherland, evidence of an arctic fauna with indications of the presence of palæolithic man. In archæology, his long and extensively illustrated account of the lake dwellings in Loch Treig is a classic description, and he was engaged on further work of this type at the time of his death.

Ritchie's activities were as wide as his interests. From its first inception in 1909, he took a great part in the development of the Royal Scottish Zoological Society, of which he became vice-president; he was secretary and later president of the Royal Physical Society; vice-president of the Scottish Marine Biological Association; chairman of the Council of the Royal Scottish Geographical Society; president of Section *D* (Zoology) of the British Association in 1939. He was for fourteen years editor of the *Scottish Naturalist* and was the natural choice as chairman of the Scottish Wild Life Conservation Committee which prepared the way for the establishment of the Scottish Committee of the Nature Conservancy, of which he was an initial member. Elected to the Royal Society of Edinburgh in 1916, he served many times on its Council, being secretary, later a vice-president and finally, in 1954, president. He was awarded the Keith Prize of the Royal Society of Edinburgh in 1944, was created C.B.E. in 1948 and received the honorary doctorate of laws from his own University of Aberdeen in 1952.

By his writings, his lectures to university students and to a wider public, and by his charming watercolour paintings of the Scottish landscape, James Ritchie was widely known, and his loss will be felt far beyond the circle of his friends and colleagues. He married Miss Jessie J. Elliot, who died in 1933, and is survived by his son, Prof. A. E. Ritchie, Chandos professor of physiology in the University of St. Andrews, and by his two daughters.

C. M. Yonge

Dr. T. A. Sprague

Dr. Thomas Archibald Sprague, well known as a taxonomic botanist and an authority on plant nomenclature, died at his home in Cheltenham on October 22, at the age of eighty-one

He took the degree of B.Sc. at Edinburgh, under Prof. Bayley Balfour. In 1898, he undertook, with Captain H. W. Dowding, R.N., an expedition to Venezuela and Colombia, and the first set of the plants he collected are at Kew. Sprague was appointed to the staff of the Herbarium of the Royal Botanic Gardens, Kew, in 1900, and for about two decades was in charge of the Thalamiflorae and Disciflorae (in the system of Bentham and Hooker). The division of work was, however, not strictly adhered to, and some of Sprague's best taxonomic work concerned the Loranthaceae of tropical and south Africa, for the "Flora of Tropical Africa" and the "Flora Capensis", respectively, and the Bignoniaceae. Later, he was in charge of the American collections. He made, with Mr. (later Dr.) John Hutchinson, a botanical excursion to the Canary Islands in the summer of 1913. He served with the artillery in the First World War and was stationed in India and did some plant collecting in the Punjab. Sprague was awarded the degree of doctor of science by the University of Edinburgh in 1930 and was, the same year, appointed deputy keeper of the Herbarium. He was a fellow of the Linnean Society of London from 1903, and on May 12, 1937, was presented with the Coronation Medal of George VI. He retired from his post at Kew on October 31, 1945.

Soon after his return from military service, Sprague devoted a large proportion of his official and private time to botanical nomenclature and to the study of certain herbals. Those who knew his careful critical researches on the systematics of various groups tended to regret that he did not concentrate on herbarium taxonomy in the form of monographic work. However, he was mentally and temperamentally well equipped to deal with modern revisions of old herbals and with the intricacies of nomenclature. His accounts of "The Herbal of Otto Brunfels" (*J. Linn. Soc. Bot.*, 48, 79; 1928) and, with E. Nelmes, of "The Herbal of Leonhart Fuchs" (*loc. cit.*, 48, 545; 1931) are models of their kind. For a good many years Sprague was in charge of compilers engaged in preparing the supplements (usually quinquennial) of the "Index Kewensis". There is no doubt that his training of these to the degree of accuracy on which he insisted greatly raised the standard of this important work. It is probable, too, that this supervision of an index to plant names directed his attention to botanical nomenclature in general and to various weaknesses in the International Rules. He attended the International Congress of Plant Sciences, held at Ithaca, New York, in August 1926 and read a paper there under the title "Principles and Problems of Plant Nomenclature". This clearly written paper (published in the Proceedings, 2, 1422; 1929) might be read with advantage by modern nomenclaturists. Sprague became a leader in plans for revision of the rules and largely directed the meetings and debates on this subject at the International Congresses of Cambridge (1930), Amsterdam (1935), and Stockholm (1950). His lucid mind and his undoubted liking for legal form enabled him to enjoy discussions which were sometimes prolonged and sometimes heated.

Sprague was very helpful in training young systematists at Kew, and, though he sometimes flared up rather quickly, he was always kind and painstaking, and anger died quickly and left no malice in him. He was twice married and leaves three children and a widow. After his retirement to Cheltenham he devoted a good deal of time to his hobby of collecting certain special makes of British ceramics and to the Cotteswold Naturalists' Field Club, of which he became president. W. B. TURRILL

NEWS and VIEWS

Jodrell Bank Radio Telescope Appeal

AN appeal was launched by the University of Manchester at the recent meeting of the Court of Governors for subscriptions to a fund for the radio telescope at Jodrell Bank. The appeal has now been issued over the signatures of Sir Raymond Streat (chairman), Mr. L. P. Scott (deputy chairman), Mr. A. V. Symons (treasurer), Mr. R. B. Barclay (deputy treasurer), and Prof. W. Mansfield Cooper (vice-chancellor). In consequence of the Russian *Sputnik* and the American *Explorer* satellites and lunar probe, all the world knows that the University of Manchester has pioneered in the construction of this 250-ft. steerable radio telescope capable of scientific research on a vast cosmological scale as well as studies of immense practical importance in radio communications and the tracking of satellites used for space exploration. When the building of the instrument was originally proposed, the Council of the University gave enthusiastic support to the ideas of the scientists. Undismayed by the large sums of money involved according to the first estimates—and the difficulties of estimating are obvious—the University embraced the project. The Nuffield Foundation and the Department of Scientific and Industrial Research agreed each to find £200,000. Later it was found essential to revise the first estimates and the Department contributed a further £130,000 on the assumption that the University would find donors willing to cover the balance. It now appears that the University will require at least £150,000 to relieve the telescope from debt and to set scientists free to pursue, without financial anxieties, work of the first order of importance and urgency. If a larger sum were obtainable, further and better work could be done. It is hoped to receive contributions not merely from firms whose products give them a technical and perhaps commercial interest in the work of the Telescope but also from firms, institutions and individuals who would not wish that the result of the University's courage in this matter should be to leave it with unsolved financial problems.

The radio telescope is an immense achievement whether viewed as a stupendous piece of scientific equipment conceived by Prof. A. C. B. Lovell, an unparalleled feat of engineering designed by Mr. H. C. Husband or a fine accomplishment by the many firms engaged on the project, especially the main contractors, the United Steel Companies, Ltd. The increases over the earliest estimates have been accepted as necessary in all the circumstances by both the Department of Scientific and Industrial Research and the University. Indeed, when the University first realized that heavy additional costs were involved, it was nevertheless decided to proceed with the instrument. In reaching this decision, the University relied on the most expert external advice, scientific and technical. As a consequence the instrument was ready to play the part it did in the International Geophysical Year and the developments which have stemmed therefrom. Had the University failed to proceed, Great Britain's contribution to recent world scientific events of great international importance would have been sensibly lessened. The ultimate costs would also have been greatly enhanced. The result of the University's courage is that Britain is first in the field with a telescope of fantastic quality at a cost far below what others will soon be paying for similar instruments. Before opening the appeal, £10,000 was received from Henry Simon, Ltd., and an offer of a further £10,000 from Simon Carves, Ltd. Several small subscriptions have been received from individual donors after Press accounts of the Court meeting. Contributions in the form of seven- or ten-year covenants will be especially welcome. The Bursar of the University will acknowledge donations or supply information to those considering alternative methods of giving support.

The National Research Development Corporation

THE Development of Inventions Bill, which received its second reading in the House of Commons on November 14, extends the power of the National Research Development Corporation to make advances by a further ten years from June 1959 onwards, and raises the limit on the amount of advances from £5 million to £10 million. In moving the second reading, the Parliamentary Secretary to the Board of Trade, Mr. J. Rodgers, explained that unless the former limit was raised, the Corporation would have to abandon many projects already in hand before they could come to fruition and might quite soon find itself unable even to discuss new projects with inventors or research organizations, however important their proposals. Mr. Rodgers also said that it is hoped in future to publish the annual report of the Corporation rather earlier. He referred to the contribution of the Corporation to the establishment of an electronic computer industry in Britain, and also mentioned its sponsoring of the flexible containers for transporting oil developed by research at the University of Cambridge. He said that the Corporation's income had now risen to nearly £200,000. Mr. A. Albu, in welcoming the Bill, mentioned among other new developments a new mechanism for storing energy in the flywheel of a commercial vehicle when braking and making the energy available afterwards for acceleration, and Sir Thomas Merton's diffraction gratings at the National Physical Laboratory, which will have increasing use in spectrometry and metrology. He believes the Corporation should use to the full its power to place development contracts, particularly for new processes or for new machines; that more use should be made of the section of the 1948 Act which enables the Government to ask the Corporation to undertake work which is not economic and for which it would make good a loss if the work was in the public interest; and that the Corporation would further develop its existing good collaboration with the universities and the colleges of technology.

Research and Development in Government Establishments

ANSWERING a question on November 18 in the House of Commons as to the availability of research equipment at the National Chemical Laboratory, Mr. H. Nicholls, Parliamentary Secretary to the Ministry of Works, on behalf of the Lord President of the Council, said that subject to the avoidance of undue interference with its own research programme, the Laboratory is always ready to consider how its resources of equipment and knowledge of special techniques can be utilized by other scientists from industrial laboratories. During the past two years, research workers from seven organizations have spent in all ninety days on experiments with special high-pressure and high-temperature equipment in the Laboratory, and this use is expected to grow. In reply to further questions about scientific and industrial research, Mr. Nicholls said that Government expenditure on scientific research for civil purposes has more than doubled since 1951, and this year the research councils for which the Lord President is responsible will be spending about £20 million, compared with less than £9 million eight years ago. The investigation at the Water Pollution Research Laboratory of the effects of industrial effluents on streams, with the object of developing improved methods of treatment, has been assisted by a contribution from industry through the Federation of British Industries which next year will amount to £13,000. The Pest Infestation Laboratory has developed a rapid and reliable instrument, now available commercially at a cost of about £50, for determining the moisture content of cereals stored in bulk, and the National Institute of Agricultural Engineering of the Agricultural Research Council has examined the range of moisture meters available for testing the moisture content of grain stored on the farm. The Road Research Laboratory is investigating means of electrically heating road surfaces to mitigate dangers from frost, and it is hoped shortly to lay another experimental surface of this type on a new road-bridge to be constructed at Slough. The work of the Laboratory on the design and siting of snow fences has been outstandingly successful and offers large savings of cost and labour if the snow fences are correctly sited. The British Coal Utilization Research Association has shown that with proper mechanical firing equipment the efficiency of use of small coal in shell-type boilers can be high. Further research and development on automatic handling and control are in progress, in association with the National Coal Board, which is also developing work on the manufacture of briquettes from small coal.

Science and Mathematics in Schools

IN answer to a question asked in the House of Commons on November 18, the Joint Under-Secretary of State for Scotland, Mr. N. Macpherson, said that according to estimates by the education authorities and managers of grant-aided schools, 97 teachers with first- or second-class honours degrees were required in October 1957 to teach science and 119 to teach mathematics. A further 152 graduate teachers were needed to teach these subjects in the junior classes of secondary schools. Representations for the release from National Service of third-class honours graduates in science and mathematics to enable them to return to the schools are under consideration.

Broadcasting, Television and the Schools

IN an address to the School Broadcasting Council on November 7, Sir Ian Jacob, director-general of the British Broadcasting Corporation, referred particularly to the dependence of Great Britain, and possibly its survival, upon the widest possible diffusion of scientific skills and knowledge. He suggested that the British Broadcasting Corporation might be able to make, in its own way, "a new and massive contribution to the understanding of science in the secondary modern schools, where the need perhaps is greatest and where the shortage of good teachers is likely to be most acute". Sir Ian said he had recently received a deputation comprising the Presidents of the Royal Society and the British Association and the Chairman of the Advisory Council on Scientific Policy, who had come to urge that the Corporation should do its best to interest the broad mass of the people in scientific development and to present science as vital to the well-being of our contemporary world. The B.B.C., he said, is already doing this job, and it proposes to put all the resources it can behind it. The task must begin in the schools, and Sir Ian thought that television might be opening up wholly new possibilities in school broadcasting.

Extensions to the Duncan Flockhart Research Laboratories, Edinburgh

EXTENSIONS to the Duncan Flockhart Research Laboratories in Edinburgh, which were opened on November 14 by Prof. John Bruce, president of the Royal College of Surgeons of Edinburgh, consist of additional development and biological laboratories. The former are in the chemical laboratory building, which also houses the analytical control department and the library. The new biological laboratories form part of a quadrangle of buildings in which biological research and assay are carried out. The extensions were designed by members of the staff, the principal contractor of laboratory furnishing being Nathaniel Grieve. Lord Ferrier, chairman of the T. and H. Smith Group of companies, of which Duncan Flockhart became a member in 1952, presided at the opening ceremony, and an address of thanks to Prof. Bruce was delivered by Dr. F. R. Smith, director of Duncan Flockhart and Co., Ltd., who is in charge of the Group's research and development activities.

The research staff includes chemists, biologists, pharmacists and a medical unit headed by a physician. The chemists are concerned with new compounds with biological activity which may become new drugs for use as analgesics, local anæsthetics, muscle relaxants and for the treatment of diseases involving nervous and muscular defects. They work in close association with the biologists responsible for testing the new compounds for their potency, absence of side-effects, etc. The pharmacists work on the presentation of drugs to ensure maximum effect and convenience for doctor and patient and on problems of stability and analysis. The medical unit makes arrangements for the clinical trials of new drugs. An extensive library is maintained which acts as an information centre for the research staff and the other technical staff of the Company.

National Science Foundation Co-operative Graduate Fellowships

THE National Science Foundation has announced a new programme of co-operative graduate fellowships under which approximately 1,000 fellowships will be offered to graduate students in the sciences and engineering. To be eligible, candidates must be citizens of the United States and have special aptitude for advanced training and productive scholarship in the sciences. This programme is in addition to the Foundation's regular predoctoral, postdoctoral, senior postdoctoral and science faculty fellowship programmes. In the first experimental year of operation, applicants may apply to study at one of 115 designated colleges and universities. Applications will be forwarded—together with the institution's recommendations—to the National Science Foundation, where they will be considered by panels of scientists appointed by the National Academy of Sciences—National Research Council. Fellows will receive a basic annual stipend of 2,200 dollars with the option of nine or twelve months tenure. Supplemental support may be extended by the institutions themselves to encourage Fellows to undertake limited teaching responsibilities during tenure of their fellowships. In addition, the Foundation will provide each institution, in lieu of tuition fees, with a fixed amount for each co-operative graduate Fellow at that institution. Co-operative graduate fellowships will be offered in the mathematical, physical, medical, biological and engineering sciences, as well as in anthropology, psychology (excluding clinical psychology), and in certain social sciences, including geography, mathematical economics, econometrics, demography, information and communication theory, experimental and quantitative sociology, and the history and philosophy of science.

National Museum of Canada

THE report of the National Museum of Canada for 1955–56 (pp. iii+140 (17 plates). Ottawa: Queen's Printer, 1957. 1.50 dollars) is far more than a formal report on the work of the institution, for it also includes papers on research work undertaken by or in collaboration with the staff. The record of the general activities includes an impressive amount of educational work carried out through the media of exhibits, lectures, publications, photographs, film strips and correspondence. Visits to the Museum by organized groups were also encouraged, and some 4,000 individuals attended the Museum in this way. Each group was provided with a guide. The papers published in this report include such diverse subjects as archæological work on Southampton and Walrus Islands, Tertiary mollusca from Princeton, British Columbia, Paleocene mammal teeth from Alberta and a bibliography of Canadian anthropology for 1955.

Equipment for Archæology and Geology

MESSRS. P. J. DUTT AND CO., LTD., of Alfred Place, Store Street, London, W.C.1, have recently issued a comprehensive and fully illustrated catalogue entitled "Equipment for Archæology and Geology", in which the emphasis is perhaps on geology rather than archæology, though the requirements of archæologists are by means neglected, being often coincident with those of geologists. All branches of geology are catered for, including both field and laboratory work, mineralogy, petrology and palæontology. The soil scientist, too, will find some of the items listed of interest. The instruments and equipment are grouped under the following headings: collecting; mapping and surveying; specimen preparation, display and preservation; laboratory equipment, including microscopes; and teaching aids. The catalogue covers a wide variety of field and laboratory activities, and should prove useful to both amateur and professional geologists, archæologists and museum curators. Messrs. Dutt also point out they are agents for Ward's Natural Science Establishment, New York, and Soiltest Incorporated, Chicago, from whom they are prepared to import specialities not available in the United Kingdom.

Rheology Abstracts

VERY soon after the British Rheologists' Club was started in 1940, its first *Bulletin* appeared, "gratis, to members of the Club only". This contained notices of meetings, news of interest to members and abstracts of recent rheological papers. After the publication of the fifty-third *Bulletin* (December 1957) the sponsors, now called the British Society of Rheology, decided to change the form of publication, the *Abstracts* being issued separately from the *Bulletin*. The latter contains news for members, summaries of papers given at conferences, etc., while the former is now headed "A Survey of World Literature" (1, No. 1; May 1958. Pp. 31. Four issues a year: subscription £2 per volume of four issues. London: Pergamon Press, 1958. Published for the British Society of Rheology).

The organization of such a venture by honorary abstractors alone is no small undertaking. The coverage must depend on chance factors involving the interests of the volunteers. The Society has decided to start with the material available and to expand coverage as opportunities arise. Already, more than a hundred journals are abstracted regularly. The aim is to direct attention to papers in journals which are fairly easily obtained and understood, while giving rather fuller abstracts of worthwhile articles in obscure journals or less-known languages. The classification is under seven headings: theoretical; instruments and techniques; metals and other solids; polymers, elastomers and viscoelastic materials; pastes and suspensions; liquids; general (miscellaneous). It is a pity that attempts made some ten years ago to start an international rheology abstract journal proved abortive. To-day, several of the national societies provide excellent abstract services, a situation which results in much overlapping. Nevertheless, in existing circumstances, the British Society of Rheology had no alternative but to organize its own survey and, until an international service can be organized, the *Abstracts* in their new form should prove very valuable to rheologists both in Britain and abroad.

History of Thermometry

A VERY interesting booklet has been issued by Messrs. Negretti and Zambra entitled "A Story of Temperature Measurement" (pp. 20. London, 1958), in which the history of the thermoscope and the liquid-in-glass thermometer is outlined from the earliest times up to the most modern forms. The earliest forms of thermoscope were devised for medical purposes, and arbitrary 'degrees' of heat and cold (which were both regarded as positive qualities) were called upon to indicate a patient's condition. Measurement began early in the seventeenth century, but it is uncertain to which of three or four inventors the credit for the construction of the first thermometer is to be ascribed. In the earliest instruments, variations in the volume of air enclosed in a bulb were used to indicate changes in temperature, but ignorance concerning the effect of atmospheric pressure vitiated their use for precise scientific purposes. The present-day forms of liquid-in-glass thermometer—the Fahrenheit, Réaumur and Celsius—appeared almost simultaneously early in the eighteenth century, and the circumstances of their invention, which have been widely misrepresented, are accurately described. The account is enriched by a large number of illustrations, many of which show instruments to be seen at the Science Museum, South Kensington, and by a useful bibliography. It can be recommended as a readable and trustworthy summary of an interesting chapter in the history of science.

Royal Australian Chemical Institute: Officers

MR. L. W. WEICKHARDT, technical director of Imperial Chemical Industries, Australia and New Zealand, Ltd., has been elected president of the Royal Australian Chemical Institute for 1958–59, and Mr. W. H. Wainwright has been elected vice-president. The other members of the Council are Mr. W. S. McGowan and Mr. C. I. Cox (New South Wales); Dr. J. M. Harvey and Dr. H. E. Dadswell (Queensland); Mr. R. G. Cooke (South Australia); Mr. J. L. Flounders and Dr. J. A. Allen (Tasmania); Dr. D. R. Zeidler and Dr. A. L. G. Rees (Victoria); Dr. D. E. White and Mr. L. R. Allison (Western Australia); Dr. A. Walkley (honorary general secretary); and Mr. G. Junck (honorary general treasurer).

University News:

Birmingham

THE title of reader in physics has been conferred on Dr. J. H. Fremlin, senior lecturer in physics, and that of reader in comparative neurology on Dr. J. T. Eayrs, senior lecturer in neuro-anatomy and at present Henry Head Research Fellow of the Royal Society in the Department of Anatomy. Approval has been given for the establishment of a chair of organic chemistry within the Department of Chemistry. The following appointments have been made: Dr. G. V. Chester, to be lecturer in mathematical physics; Dr. M. H. Cardew and Dr. M. B. King, to be lecturers in chemical engineering.

Bristol

THE following appointments have been made: Miss Dorothy J. Cooper, to be lecturer in education; and Dr. A. J. Forty, to be lecturer in physics.

The following gifts, among others, have been received by the University: a legacy from Mrs. Hilda Grace Pickard of her residuary estate (subject to three life interests) upon trust to create an endowment fund and to apply the income for the purpose of research into the alleviation of cancer, to be named the Pembery Research Trust—funds totalling £10,084 representing approximately two-fifths of the total residuary estate have now been transferred to the University; £6,300 from the Department of Scientific and Industrial Research to the Department of Physics towards the cost of Prof. C. F. Powell's research on heavy mesons and hyperons by the photographic method; grants totalling £6,086 from the Department of Scientific and Industrial Research to the Department of Physics for salaries and equipment for research work under Prof. Powell; £1,100 from the National Coal Board to the Department of Physical and Inorganic Chemistry for a continuation of the study of reactivity of carbon surfaces with oxygen; and £1,700 from the Department of Scientific and Industrial Research for research assistants and equipment; £1,315 from the Ministry of Supply to the Department of Aeronautical Engineering for research on the prevention of flutter by damping; £1,000 from the Agricultural Research Council to the Department of Veterinary Medicine for research on the nutrition of the baby pig; and £1,000 from the Nuffield Foundation to the Department of Veterinary Anatomy for research on age changes in the vertebral disk of the cat.

London

SIR JOHN ATKINS has been admitted as the first Fellow of Queen Elizabeth College in recognition of his unique service. It is to his vision and determination that the College owes its existence, and he has worked for it continuously since 1911 when, as honorary secretary of the Appeal Committee, he inspired a few generous benefactors to subscribe the funds needed for the erection of the present buildings. He remains a member of the Governing Body, to which he was elected in 1912 and of which he has been chairman since 1922. He is being succeeded as chairman by Sir George Allen, secretary of the British Association.

In the paragraph on 'Commonwealth Fellowships' in *Nature* of November 8, p. 1276, the percentage of overseas students at the Imperial College of Science and Technology, London, was quoted as 38, a figure which has been reported previously in the Press. The Registrar of the College states that this refers only to postgraduate students (full-time and part-time). The percentage of undergraduate students from overseas is only 10 per cent. The total number of full-time overseas students has been rising steadily since the programme of expansion started in 1953, but the proportion has scarcely changed. In 1952–53 there were 312 from overseas out of a total of 1,653 full-time students, or 19 per cent. Last session the corresponding figures were 528 out of 2,437, or 22 per cent. The number this term is 552 out of 2,580, or 21 per cent.

The Night Sky in December

NEW moon occurs on Dec. 10d. 17h. 23m. U.T., and full moon on Dec. 26d. 03h. 54m. The following conjunctions with the Moon take place: Dec. 22d. 05h., Mars 4° N. Mercury rises about two hours before the Sun at the end of the month, but conditions are not favourable for observation. Venus is too close to the Sun for observation. Mars sets at 6h. 05m., 4h. 55m. and 4h. 00m. at the beginning, middle and end of the month, respectively. Mars retrogrades until December 20, after which date it resumes its eastward motion among the stars; it is in Aries throughout December. Its stellar magnitude decreases during the month from $-1\cdot6$ to $-0\cdot6$, its distance from the Earth increasing from 49 to 67 million miles. Jupiter rises at 5h. 50m., 5h. 10m. and 4h. 25m. on December 1, 15 and 31, respectively; it is east of α Libræ. The stellar magnitude of Jupiter is $-1\cdot3$; conditions for observation are not very favourable. Saturn is too close to the Sun for observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Dec. 23d. 22h. 33·6m., δ Tau. (*D*); Dec. 23d. 23h. 03·2m., 64 Tau. (*D*); Dec. 28d. 20h. 29·2m., A^1 Cnc. (*R*); Dec. 29d. 04h. 04·0m., α Cnc. (*D*); Dec. 29d. 04h. 59·8m., α Cnc. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The Geminid meteors are active during December 9–14, conditions being very favourable; the radiant is near R.A. 7h. 28m., Dec. + 32°. The Ursid meteors are active on December 21, but conditions for observation are unfavourable. The winter solstice occurs on Dec. 22d. 09h.

Announcements

ON November 22, H.M. the Queen conferred the Order of Merit on Viscount Samuel. This award is a tribute to a life-time of devoted public service, including fifty years as a Privy Councillor.

DR. VITTORINO VERONESE, a lawyer and formerly president of Catholic Action in Italy, has been elected director-general of the United Nations Educational, Scientific and Cultural Organization for a period of six years.

THE managing trustees of the Drummond Trust will consider, in March 1959, applications for a Drummond Fellowship for research in nutrition. It may be a Senior or Junior Fellowship, depending on the qualifications of the person selected. The value of a Senior Fellowship would be £1,100 per annum with expenses grant and superannuation, and of a Junior Fellowship £500 per annum with expenses grant. The Fellowship will normally be tenable for two years. Full particulars can be obtained from the Honorary Secretary, Drummond Trust, University College London, Gower Street, W.C.1. Completed application forms must be received not later than January 31, 1959.

THE Royal Agricultural Society of England offers annually a medal together with an award of one hundred guineas for research work of outstanding merit carried out in the United Kingdom which has proved, or is likely to prove, of benefit to agriculture. Recommendations for this award can be made by the heads of university departments, research stations and institutes. No direct application by candidates will be considered. Recommendations for the next award must be submitted to the Secretary, Royal Agricultural Society of England, 35 Belgrave Square, London, S.W.1, not later than January 31, 1959, accompanied by nine copies of a brief statement of the candidate's attainments and a list of his publications.

THE fourth Biennial Conference on Carbon, on "The Physics and Chemistry of Carbon Surfaces", will be held at the University of Buffalo during June 15–19, 1959. Information can be obtained from Carbon Conference, University of Buffalo, Buffalo 14, New York.

A MEETING of the Parasitology Group, Institute of Biology, will be held in Edinburgh during March 19–23, 1959. The closing date for registration is February 28. Further particulars of the meeting can be obtained from Miss J. Mahon, Department of Zoology, Bedford College, Regent's Park, London, N.W.1.

THE Institution of Electrical Engineers is holding a Convention on Thermo-Nuclear Processes, during April 29–30, 1959. The probable range of topics is as follows: basic physics of thermonuclear processes; prototype British thermonuclear experiments; constructional features of ZETA 1; design problems of future ZETA-type systems; possibilities of direct conversion from nuclear to electrical energy. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

THE next meeting of the Plant Phenolics Group will be held on January 6, 1959, at the Queen Elizabeth College, London, W.8, under the chairmanship of Prof. R. D. Haworth. The subject will be "Chemistry of Condensed Tannins". Speakers will include Drs. B. Brown, D. E. Hathway, W. E. Hillis, E. A. H. Roberts, D. Roux and T. Swain. Further information can be obtained from the honorary secretary, Dr. T. Swain, Low Temperature Research Station, Downing Street, Cambridge.

UNDER the provisions of the Fulbright Programme, travel grants are available to citizens of the United Kingdom and dependent territories to go to the United States for an academic or educational purpose, provided that they have financial support in dollars for the visit, and have been accepted by an American institution of higher learning. Grants cover the cost of direct travel between a candidate's home and the American university or institution, and are available during June 1, 1959—April 1, 1960. Applications must be submitted by March 14, 1959 (for those travelling between June 1, 1959, and August 15, 1959) or by June 1, 1959 (for those travelling between August 16, 1959, and April 1, 1960). Application forms and further information can be obtained from the United States Educational Commission in the United Kingdom, 71 South Audley Street, London, W.1.

INTERNATIONAL ATOMIC ENERGY AGENCY

THE first annual report of the Board of Governors of the International Atomic Energy Agency to the General Conference* covers the period October 23, 1957–June 30, 1958, in which the membership of the Agency rose from twenty-six to sixty-six. Much of the work of creating the technical and administrative services needed both to implement the initial programme, which allots high priority to activities that will give the maximum benefit from the peaceful application of nuclear energy in improving the conditions and raising the standard of living of people in the under-developed areas, and to co-ordinate the Agency's activities with those of the United Nations and the Specialized Agencies, has been completed and operations commenced in some of the fields assigned by its statute. Excluding posts in the Division of Language Services, some two-thirds of the established posts in the Agency are in the scientific and technical divisions, and in the 111 professional staff appointed by June 30, 1958, twenty-eight nationalities were represented. Deputy directors-general were appointed in December for each of the three technical departments: training and information; technical operations; and research and isotopes. Experience so far has confirmed the Preparatory Commission's expectations that initial activities in regard to the supply of materials, reactors and safeguards would consist largely of planning, collecting and exchanging information, surveys and technical advice.

The major technical assistance activity already operating is the Agency's international training programme, which embraces the training of specialists in all important peaceful applications of nuclear energy by the award of training fellowships and exchanges of scientists and experts. For these fellowships a fund of 250,000 dollars was established, and in addition 268 subsidized or fully paid fellowships for training and research in institutions in their own countries were offered by member States. A field study is being made in Latin American countries to determine their requirements for training in the peaceful uses of nuclear energy and the availability of existing facilities. It is expected that the basic technical library will be functioning by the end of 1958, and the Agency's scientific and technical documentation service is already providing abstracts of scientific material and specialized bibliographies. It is also proposed to issue lists of all conferences in this field held throughout the world and to assist member States and scientific and technical organizations in planning and timing such meetings.

A provisional manual on radiation protection is planned, and an expert panel has been convened, while the collection and evaluation of data on the disposal of radioactive waste have commenced. The reactor programme will be divided into the physics and chemistry of reactors; problems of engineering; and production of nuclear energy. Data are being collected for an international reactor directory covering all types of power, research and training reactors. Under isotopes and research, plans are being made for forming composite isotope teams, including experts on applications of radioisotopes and radiation, to be sent on request to countries in the less-developed areas, and a survey is being made with a view of compiling an international catalogue of radioisotopes. The work of the Agency is further displayed in its Programme and Budget for 1959*, in which an analysis of its proposed expenditure of 6·725 million dollars (including 550,000 dollars on scientific information and conferences, 2·575 million dollars on technical assistance and 1·050000 million dollars on regulatory activities) is accompanied by a description of the functions and programme of each of its departments.

NETHERLANDS–NORWEGIAN JOINT ESTABLISHMENT FOR NUCLEAR ENERGY RESEARCH

THE sixth annual report* of the Netherlands–Norwegian Joint Establishment for Nuclear Energy Research (J.E.N.E.R.), the joint research and training centre sponsored by the Dutch Reactor Centrum Nederland (R.C.N.) and the Norwegian Institut for Atomenergi (I.F.A.), which has now been published, describes the work of the Establishment during the period July 1, 1956–June 30, 1957. The governing board consists of a joint commission comprising three Dutch and three Norwegian members, and the work of the Establishment is directed by Mr. Gunnar Randers, who was appointed by the Institut for Atomenergi with the approval of the Reactor Centrum Nederland. The staff is grouped into six divisions—physics, engineering, civil engineering, chemistry, isotopes, and health physics—in addition to the administration, and during the period under review totalled 180, of which fifty-four are classified as scientists and engineers and sixty-four as technicians and skilled workers.

The research reactor, JEEP, which is fuelled with natural uranium and moderated and cooled by heavy water and which is situated at Kjeller, was in almost continuous operation at 450 kW. during the year, and approximately 92 MW. days of energy were released. Complete shut-downs occurred only for holidays and for the semi-annual inspection work. The Halden boiling-water reactor (HBWR) which uses heavy water, and which was designed by the Establishment, is being built by the Institut for Atomenergi and is now at an advanced stage of construction; it was expected to go critical some time during 1958. The civil engineering work has been completed; the workshop in the control building has been equipped; and the offices on the first floor of the building are in use. Most of the mechanical components of the reactor are being made by Norwegian firms, but the uranium fuel will be supplied by the United Kingdom Atomic Energy Authority and the heavy water by the United States Atomic Energy Commission. The reactor will be operated at low temperatures to begin with, and preliminary investigations have shown that 2*S*-aluminium withstands these low temperatures well and therefore is suitable as canning material for the initial fuel charge.

---

* Sixth Annual Report, July 1956–June 1957, of the Netherlands–Norwegian Joint Establishment for Nuclear Energy Research. Pp. 31. (Kjeller, near Lillestrøm: JENER, 1958.)

Information concerning the probable kinetics of the reactor has been obtained through void-coefficient experiments conducted by the physics division and by the use of a reactor simulator which was built specially for this purpose. The simulator consists of an analogue computer, loaned by the Norwegian Defence Research Establishment, to which has been added various units for the simulation of reactor kinetics and xenon poisoning and a multiplier circuit.

The nuclear ship-propulsion group has concentrated its attention on the use of uranium oxide – light water lattices for ship reactors. Parametric analyses of various fuel-moderator systems have been carried out, and optimization studies of reactor plant components have been made. Problems relating to both normal as well as adverse operational conditions, such as collisions at sea, groundings, fire and explosion hazards, have been considered and discussed with the appropriate Norwegian maritime authorities.

In addition to the void-coefficient experiments the physics division has continued its exponential experiments on heavy water – natural uranium lattices which it is carrying out in co-operation with A. B. Atomenergi at Stockholm. A report of measurements on clean lattices has been published (*J. Nuclear Engineering*, 3; 1956) and a report on cluster type rods has been issued by A. B. Atomenergi (AEF–65). A Nonius general-purpose camera has been added to the X-ray equipment and X-ray work has been mainly concentrated on phosphoric acid. The investigation of capture gamma circular polarization has continued and work on the gamma-spectrum of fission has been started. The health physics service of the Establishment was intensified during the period under review and the report mentions that only one member of the staff received a dose in excess of 5r. and that 81 per cent received less than 1r. The service controls about 150 persons.

Details are also given in the annual report of the production and shipments of radioisotopes; of the activities of the chemistry and metallurgical sections of the Establishment; of the reports and publications published by the Establishment and members of the staff; of the Establishment's reactor courses and of the new reactor school being opened in 1958 with a nine-week full-time postgraduate course in fundamentals of nuclear engineering; and of the personnel and accounts of the Establishment.

RESEARCH AND DEVELOPMENT IN THE B.B.C.

APART from the maintenance and steady improvement of a nation-wide sound and television service, the manner in which the Engineering Division of the B.B.C., and particularly of its Research and Designs Departments, continues to make technical progress, is well illustrated by the B.B.C. Engineering Division Monographs, of which Nos. 15–19 have been published during the past few months* (reference was made to Nos. 12–14 in *Nature*, 181, 1046; 1958). These deal with a variety of subjects, from the quantitative measuring technique which is a necessary tool in the transmission and reproduction of high-quality sound to an appraisal of the results of the experiments made by the B.B.C. in colour television.

Monograph No. 15, entitled "New Equipment and Methods for the Evaluation of the Performance of Lenses for Television", outlines the photo-electric method of testing lenses and describes a new optical bench developed for the purpose. The factors affecting the quality of a television picture are discussed, and formulæ are developed on an experimental basis for an index of quality for both monochrome and colour television.

The analysis and measurement of the extremes of sound programme-levels are dealt with in Monograph No. 16 in two parts: (1) "Investigation of Extreme Values of Sound Pressure", by D. E. L. Shorter and W. I. Manson; and (2) "A Description of an Optical Instrument for Monitoring Sound Signals", by E. R. Wigan. An optical projection type of instrument has been developed, the range of indication of which is sufficient to deal with the most difficult programme material. While the instrument has a limited field of application to sound broadcasting, it has obvious advantages for the control of sound channels in television.

"The Design of a Linear Phase-Shift Low-Pass Filter", by L. E. Weaver (Monograph No. 17), describes the theoretical and practical details of the design of a very linear phase-shift low-pass filter intended to remove noise and other irrelevant information above approximately 3 Mc./s. from the output of a television camera control unit. A "Note on Random Fluctuation Noise in Image Orthicon Camera Tubes", by R. D. A. Maurice, is appended and revises some of the conclusions in an earlier monograph on the distribution of noise over the grey scale of a picture.

Monograph No. 18 forms an interesting highlight in the series under review and is entitled "The B.B.C. Colour Television Tests: an Appraisal of Results", by W. N. Sproson, S. N. Watson and M. Campbell. This describes the results of field trials conducted during 1955–57 in viewers' homes by the Research and Designs Departments of the Corporation after preliminary experiments and the development of suitable receivers in the laboratory. Since the tests were completed, a further series was carried out during 1957–58 and the results are now being analysed.

* B.B.C. Engineering Monographs. No. 15: New Equipment and Methods for the Evaluation of the Performances of Lenses for Television. By W. N. Sproson. Pp. 16. No. 16: Analysis and Measurement of Programme Levels. Part 1: Investigation of Extreme Values of Sound Pressure. By D. E. L. Shorter and W. I. Manson. Part 2: A Description of an Optical Instrument for Monitoring Sound Signals. By E. R. Wigan. Pp. 31. No. 17: The Design of a Linear Phase-Shift Low-Pass Filter. By L. E. Weaver. Pp. 23. No. 18: The B.B.C. Colour Television Tests—an Appraisal of Results. By W. N. Sproson, S. N. Watson and M. Campbell. Pp. 39. No. 19: A V.H.F. Television Link for Outside Broadcasts. By K. C. Quinton. Pp. 20. (London: British Broadcasting Corporation, 1957 and 1958.) 5*s*. each.

The field trials on which the B.B.C. now reports extended over a total period of seventeen months and involved the analysis of more than a thousand questionnaires, filled in by members of the B.B.C. staff and others who watched the results on special sets. So far as reception of the colour picture is concerned, the B.B.C.'s verdict is that the colour pictures produced by the N.T.S.C. system as adapted to 405 lines, with the picture sources and display tubes that are at present available, are satisfactory. The problem of registration with the three-tube colour camera requires attention, and certain features of the display tube could with advantage be improved, but the technical performance of the system is adequate for a satisfactory colour television service in the frequency bands at present in use. The tests radiated from Crystal Palace during November 1956–April 1957 included live studio performances, film and slides. Of the observers, 89 per cent regarded the reception of the live scenes as satisfactory. The 35-mm. film was regarded as satisfactory by 100 per cent of the observers, the 16-mm. film by 93 per cent, and the slides by 98 per cent. The compatibility of the transmissions was very good indeed. This means that the quality of ordinary black and white television, when received on a colour television set, was found to be generally satisfactory; and likewise the quality of the colour transmissions, when received in black and white on ordinary television sets, was completely acceptable to 94 per cent of technical observers.

The results of the tests have been communicated to the Television Advisory Committee, which has the task of advising the Postmaster-General on the whole field of television. The results have also been sent to the International Radio Consultative Committee which recently met in Moscow to consider colour television. The B.B.C. will carry out further experimental transmissions from time to time. It is pointed out that there are many other problems to be solved: for example, the production of a reasonably priced colour-receiving set and agreement on the future standards to be applied to the development of television in the United Kingdom. The decision whether or not there is to be a public service of colour television, and if so the system to be used, rests with the Postmaster-General.

A national television network requires to be adequately supported by inter-connecting line and radio links capable of transmitting without distortion the complex signals conveying the sound and vision information. Where outside broadcasts are concerned, mobile equipment is usually necessary, and the design and development of such equipment is described in Monograph No. 19, by K. C. Quinton, under the title "A V.H.F. Television Link for Outside Broadcasts". This provides, first, a brief historical introduction to the problems of radio linkage. leading to the need for using ultra-high frequencies, with particular reference to moving-camera applications and to propagation over water. The relative merits of amplitude and frequency modulation are explored in theory and practice; and details are given of the equipment developed for use in the frequency-range 610–660 Mc./s. The first year's operational experience with such equipment has been very successful.

ROAD RESEARCH

THE work of the Road Research Laboratory is concerned partly with the behaviour of traffic on the road, and partly with the performance of materials and with the methods of construction of the road itself. The Laboratory's annual report for 1957* is interesting and well presented.

Some problems of traffic and safety can be solved by a controlled experiment. For example, the Laboratory conducted a full-scale experiment with streams of traffic weaving through each other as the vehicles entered and left a roundabout. This led to an empirical formula, from which the limiting traffic flow could be predicted accurately. The Laboratory has also developed an apparatus for measuring accurately the resistance of a road surface to skidding; one graph shows a seasonal variation of this resistance which corresponds closely with the seasonal variations in the number of skidding accidents.

To study other problems, the Laboratory conducts various field surveys. For example, a survey of the flow of traffic in the streets of London and Glasgow showed an average journey-speed of ten miles per hour with vehicles stopped for about a third of their journey time. Detailed field studies of accidents suggest that the doors of British cars tend to jam in a crash, while the doors of American cars tend to fly open. Their conclusion from a study of reports of a sample of fatal accidents was that 13 or 14 per cent of fatal accidents involved a person who had drunk alcohol (the official statistics suggest a figure of only 2 per cent), and showed further that, "one half of the drivers and more than one half of the pedestrians involved in fatal accidents at night had been drinking".

Experiments to reduce accidents have sometimes been very successful: a big roundabout can eliminate three-quarters, and a smaller roundabout a half, of the accidents at an intersection. Sometimes success is more elusive. A full-scale attempt to reduce road casualties in Slough over a two-year period produced only an "apparent reduction" compared with the increasing numbers of casualties in Great Britain as a whole, which must have been something of a disappointment. Perhaps it was a mistake for the Laboratory to be too much concerned with traffic conditions in a town so close at hand.

In the work on materials and methods of construction a major experimental section of road has been constructed as part of the new north-bound carriageway of the Great North Road at Alconbury Hill in Huntingdonshire: there are seventy different variations in the pavement construction within a length of 2¼ miles, although the passing motorist is probably only aware of the changes at one or two points in this length. This experiment is concerned with fairly conventional pavement construction, but it is interesting to read of the continued satisfactory performance of some other experiments of previous years when lengths of cement-stabilized gravel base were constructed. Such a base is inherently cheaper and quicker to construct than a normal base; perhaps British engineers in the past have concentrated too much on the stabilization of the soil that happens to be on the site, and have given insufficient attention to the possibility of stabilizing low-grade unwashed gravel which may be available close by. Work on concrete and bituminous materials is also described.

---

* Department of Scientific and Industrial Research. Road Research 1957: The Report of the Road Research Board with the Report of the Director of Road Research. Pp. iv+93+8 plates. (London: H.M. Stationery Office, 1958.) 5s. 6d. net.

The report begins with an attempt to gauge the importance of the road problem in Britain. The cost of road accidents is about £100 million a year, and that of time and fuel wasted in congested traffic is several times that figure. The present programme of road improvements is based on information that appears to be inadequate as a basis for design, and in comparison with the sums of money that have been mentioned above the expenditure on road research is negligible. The civil engineering industry itself does relatively little research, and the paucity of the support which the work of the Road Research Laboratory receives can be gauged from a disturbing sentence on the Alconbury Hill experimental section which ". . . was planned some twelve years ago" but was only constructed last year. This is a straightforward experiment for which a site should have been found so that the work could be carried out well in advance of the present road-construction programme. It must be hard to continue with research that apparently receives slight encouragement, and know that for lack of design data the new roads that are now being built are probably not so good as they could be.

A. N. SCHOFIELD

JANE COFFIN CHILDS MEMORIAL FUND FOR MEDICAL RESEARCH

THE Jane Coffin Childs Memorial Fund for Medical Research, of New Haven, Connecticut, made appropriations totalling 312,779·93 dollars in support of research and fellowships in cancer for the year July 1, 1957–June 30, 1958. This brought to slightly more than four million dollars the total distributed by the Fund since its establishment in 1937.

Support is given by the Fund to research in both the basic and clinical sciences; for postdoctoral fellowships providing opportunity for advanced training and research; and for conferences and meetings of national and international societies concerned with cancer research. Among publications to the support of which the Fund has contributed since it helped to establish them are the journal, *Cancer Research*, and the "Atlas of Tumor Pathology".

Applications for research grants and fellowships are reviewed by the Board of Scientific Advisers, directed by Dr. M. C. Winternitz, three times a year at the offices of the Jane Coffin Childs Memorial Fund for Medical Research, 333 Cedar Street, New Haven 11, Connecticut.

Although most of the Fund's grants are given to American investigators, no geographical restrictions are placed on its allocations. Austria, Britain, France, Japan and Sweden are represented on the current list of grants for 1958. Dr. Bengt E. G. V. Sylvén, associate professor of experimental cancer research in the Karolinska Institute at Stockholm, received a first grant (30,000 dollars for three years) for development of cytochemical methods to be used in attacking a long-standing controversial question in cancer—the relation of proteolytic enzymes in the malignant cell to the penetration of surrounding tissues by cancer. Dr. Jacques Monod, director of the Department of Cellular Biochemistry at the Pasteur Institute, Paris, received a fifth grant (totalling 29,400 dollars since 1954) for studies of specific enzymes involved in the selective penetration of certain organic molecules into bacterial cells. Grants made to the Institute of Cancer Research, Royal Cancer Hospital, London, beginning in 1938 when the late Sir Ernest Kennaway, then director of the Institute, visited the Fund in New Haven, now total 73,500 dollars. American investigators supported by the Fund in 1958 were working chiefly in university and medical school departments of the basic and clinical sciences, ranging from genetics and botany to surgery and medicine.

Among the long-term programmes at present supported by the five-year grants is that of Dr. Charles B. Huggins and his associates (25,000 dollars a year) at the Ben May Laboratory of Cancer Research, University of Chicago.

In accordance with the developing trend in most of the research on cancer, biochemical approaches outnumber all others in the work of both investigators and Fellows supported by the Fund, with especial concern for the chemical reactions in normal and neoplastic cells and tissues and with particular interest in protein and nucleoprotein metabolism. These and other chemical approaches to the problems of cancer were being studied in tumour and other viruses, in immunological mechanisms, in connexion with the steroid hormones.

Among other grants made by the Fund for the first time in 1958 are those to Dr. L. L. Engel (Massachusetts General Hospital) for work on methods for studying urinary steroid metabolites in cancer; to Dr. E. H. Stotz (University of Rochester) to investigate the occurrence and role of peroxidase in proliferating tissue and its response to hormones; to Drs. R. W. McKee and H. Cook (University of California) for work on physico-chemical and biological characterization of nucleic acids and proteins from several different ascites tumours; to Prof. J. N. Davidson (University of Glasgow) to investigate nucleic acid metabolism in cancer tissue; to Dr. Osamu Hayaishi (Kyoto University) for work on the biological synthesis and degradation of peptides and proteins; and to Dr. Stanfield Rogers (University of Tennessee) to investigate the mechanism of action of the Shope papilloma virus in producing papillomas in rabbit epithelium.

New Fellows supported by the Fund in 1958 include Dr. P. Ottolenghi (Copenhagen), Dr. G. L. Hagen (Harvard), Dr. M. Richter (Indiana), Dr. L. Del Gatto (California), Dr. E. V. W. Yamada (U.S. National Institute of Arthritis and Metabolic Diseases), Dr. K. R. Hanson (New York), Dr. Monto Ho (Harvard), Dr. D. Rubinstein (Michael Reese Hospital, Chicago), Dr. A. Iodice (University of California, Berkeley), Dr. E. A. Carusi (California Institute of Technology), Dr. J. Rothschild (Rockefeller Institute for Medical Research), Dr. J. B. Mudd (University of California, Berkeley).

GULBENKIAN FOUNDATION, LISBON

GRANTS FOR 1958

THE Trustees of the Calouste Gulbenkian Foundation, Lisbon, have announced a list of grants made during 1958 and amounting in total to nearly £1 million. The two previous lists of grants, issued in April and November 1957, totalled £1½ million. Out of this year's grants the British Isles and the Commonwealth overseas receive more than £200,000.

The list of grants includes: £42,000 to the Old Bodleian Library, Oxford, for restoring the fabric of this building, begun in the fifteenth and completed in the seventeenth century; £30,000 to Fort Jesus, Mombasa, for the restoration of the sixteenth century Portuguese fort and its conversion into a museum of East African history and archæology under the care of the Royal National Parks of Kenya; up to £6,000 over three years to the International Institute for the Conservation of Museum Objects; £1,500 to the Welsh Folk Museum for recording equipment for a survey of Welsh oral traditions of the countryside, including the domestic, agricultural and craft vocabularies, before they disappear under the impact of modern technology; £32,500 to the Centre for Nuclear Energy Research, Portugal, for equipment, and running costs for three years, for its mass spectrometry and isotope section; to the University of Coimbra, (*a*) the Chemical Laboratory, £12,430 for a spectrophotometer and expensive books, (*b*) the Physics Laboratory, £6,200 for analyser and other equipment for atomic energy research, (*c*) the Galenic School of Pharmacy, £3,020 for apparatus for electrophoresis and chromatography, (*d*) the Institute of Geophysics, £1,750 for scientific equipment; £14,375 to the Bento da Rocha Cabral Institute for Scientific Research for equipment and three years research expenses; £12,850 to the Centre for Research in Infectious Diseases, Portugal, for capital and running costs for three years; £11,250 to the Centre for Economics and Statistical Research, Portugal, over three years, for seminars and training of future research workers; £4,170 to the National Agronomy Station, Portugal, for books for the library; £3,750 to the Egas Moniz Research Centre, St. Mary's Hospital, Lisbon, for fellowships; £2,000 to the University of Lisbon Botanical Garden and Laboratory, for microfilm reader, microscopes and transport for field-work; £1,250 to the Organic Chemistry Laboratory, Higher Technical Institute, Lisbon, for equipment; £1,080 to the Hospital of Dona Estaphania, Lisbon, for scientific meetings organized by the head of the Department of Child Health.

Scholarships and other grants for education or study at home or overseas for the year 1958–59 include: £112,500 for Portuguese students and scholars, £20,000 for Armenian students, and £10,000 for scholars, research workers, etc., and £15,000 for Middle East students. In the United Kingdom £4,030 was spent in 1958.

Other grants include £50,000 to Churchill College, Cambridge, to endow three Gulbenkian studentships for graduates of universities outside the United Kingdom; up to £3,750 to the Institute of Archæology, University of Coimbra, and other archæological bodies; £3,000 to the Department of Education, Oxford, directed by Mr. Alec Peterson, to enable a study to be made of specialization in schools and its real relevance to university requirements, and then to attempt to draft an ideal syllabus and timetable for a combined arts and science sixth form; £350 a year for three years to the Egypt Exploration Society and Ashmolean Museum, Oxford, for a technician to be trained (by the reader in papyrology in the University of Oxford) in the technique of piecing together fragments of ancient papyri by matching the fibres instead of the text; £600 over two years to Prof. Christopher Hawkes (University of Oxford) for visits to Portugal at the invitation of the Ministry of National Education to collaborate with Col. Mario Cardoza of Guimarães in the excavation of early Celtic *castros* and in the training of Portuguese archæologists in the latest techniques of excavation; £700 to the Department of Economics, University of Bristol, for a study of the 'employability' of workers who have suffered long-term unemployment due to ill-health. Out of funds set aside in 1957, the Foundation has assisted one undergraduate scientific expedition this year, namely, the Westminster Hospital Medical School's expedition to the Belgian Congo. In addition, the Royal Geographical Society, London (which already lends surveying instruments to expeditions), has accepted £1,200 for a pool of other instruments and equipment for loan to university expeditions.

BIOCHEMICAL RESPONSE TO PHYSICAL INJURY

A SYMPOSIUM on "The Biochemical Response to Physical Injury" was held at Semmering, Austria, during September 7–12 under the ægis of the Council for the Organization of Medical Sciences with the assistance of the Wellcome Trust and the International Union of Biochemistry. Radiation injury was excluded from discussion.

Dr. D. P. Cuthbertson (Scotland) acted as chairman and Dr. H. B. Stoner (England) was technical secretary. The general and local arrangements were respectively in the hands of Dr. J. F. Delafresnaye (Council for the Organization of Medical Sciences) and Dr. F. G. Wewalka (Austria).

F. A. Fuhrman (United States) opened with a description of "Electrolytes and glycogen in injured tissues". He pointed out that we know more about the electrolyte pattern and its control in skin and skeletal muscle—which constitute 70 per cent of the mass of the soft tissues of the body and which are more frequently injured than other tissues—than in any other. The main difficulty, however, is our inability to determine precisely the size of the extracellular space in injured tissue. The replacement of intracellular potassium by sodium following injury is of very great interest and appears to be due to failure of the sodium pump rather than to death of cells. It is not known how long intracellular sodium must be present to be harmful; or, indeed, whether it ever does become harmful. At least eight different enzymes are activated by potassium and inhibited by sodium. Abnormal carbohydrate tolerance has been demonstrated in potassium-deficient animals in which part of the intracellular potassium was replaced by sodium. But much more information is necessary before the electrolyte changes in complex injuries can be causally related to alterations in physiological function.

J. Trémolières and R. Derache (France), in "Metabolism of nucleotides and phosphate in injured tissue", described the uniformity of the local response to injury as exemplified by the fact that the changes in the acid-soluble phosphorus compounds go on in nearly identical ways whatever the injury (radiation excepted). There is a reduction of energy-rich compounds (phosphocreatine and adenosine triphosphate) as in anaerobic conditions. Beyond a certain point cellular lesions become irreversible. These investigators then described the state in anoxic ischæmia and of revascularization. They suggest that local œdema can be explained by a fall in the protein - adenosine triphosphate complexes which are able to select between potassium and sodium. Necrosis and irreversible proteolysis can be related to the structural functions of adenosine triphosphate in mitochondria and proteins.

"The endogenous substances inducing pathological increases in capillary permeability" were considered in two papers by A. A. Miles and D. L. Wilhelm (England), who discussed the activation of endogenous substances increasing capillary permeability (Miles), and the evaluation of the role of endogenous permeability (Wilhelm). They emphasized that among the early responses to injury, the inflammatory reaction is paramount. In their view, in our present state of knowledge it is almost impossible to analyse the factors operative in a long-lasting and severe inflammation, and progress in this field is most likely to be achieved by studying the essential reactions of inflammation induced by minimal stimuli. Judging from the large number of relatively simple substances which can increase permeability, it is possible that the tissues use one or several of a variety of endogenous substances as mediators, and that these differ according to the type of injury. In certain circumstances and certain animals, histamine and 5-hydroxytryptamine appear to be mediators. These workers could not subscribe to the view that, since endogenous leukotaxine, globulin permeability factor and so forth are there, they must in consequence play some part in permeability changes, otherwise they would not be there. Their view is that even supposing all endogenous substances in the body have their proper and necessary role in the living tissues, the biological activities in terms of which we choose to identify and explore them may be wholly irrelevant to the function they fulfil in the body.

A. Fonnesu (Italy) described "Changes in energy transformations as an early response of the cell to injury". The well-known histological picture of cloudy swelling is the morphological result of these changes—a condition described by Rudolph Virchow in 1871 as a kind of acute hypertrophy with tendency to degeneration. The features of this condition are as follows: (1) an alteration of the mitochondria which follows, or is followed by, a partial inhibition of phosphorylation coupled with oxidation; as a consequence, aerobic glycolysis increases; (2) increased protein synthesis. Assuming the mitochondrial alteration is the first response of the cell to injury, this may be the cause of an increase of aerobic glycolysis and an increase of inhibition. No answer can be given as to how impairment of oxidative phosphorylation can lead to an enhancement of an endoergonic process such as protein synthesis. Other conditions, in pathology, are known in which the uncoupling of oxidative phosphorylation is accompanied by an increase of both glycolysis and protein synthesis.

Concerning the more general response to injury, "The effect of limb ischæmia on carbohydrate distribution and energy transformation" was analysed by H. B. Stoner and C. J. Threlfall (England). It appears that during the period of limb ischæmia and for the first part of the survival period afterwards, the brain, liver, heart and uninjured muscle are adequately oxygenated and the metabolic changes in these organs cannot be attributed to hypoxia. The secretion of the adrenal medulla in response to the injury is the main cause of the altered carbohydrate distribution. The mechanism of the changes in energy transformations which occur at this time is not yet understood.

In the estimation of these investigators the ability of the animal to withstand the injury is probably decided during this early period and it is possible that the biochemical changes which occur are part of a defensive mechanism. If the animal is unable to withstand the injury, oxygen transport fails during the later part of the survival period and the resulting tissue hypoxia leads to the terminal changes in energy (heat) production and carbohydrate metabolism.

A. G. B. Kovách (Hungary), in a paper on "Metabolic responses to injury in the cerebral tissues", described the favourable effect of perfusion of the brain with normal blood in hæmorrhagic and ischæmic shock. The functional changes as tested by electrocorticographic investigations support the hypothesis that impairment of the nervous system plays an important part in the development of shock. The oxygen consumption of the brain—its oxygen requirement—does not decrease during shock, in fact it rises, in spite of the fact that the circulation in the head is deficient. Unlike muscle where the glucose uptake is lessened after shock, the brain remains unchanged in this respect, to the terminal stage, when it diminishes. The hexokinase activity in the brain of the animal in shock increases, whereas in muscle it is slowed up. On the other hand, cerebral anoxia (stagnant or arterial) lowers the brain hexokinase activity. These and other changes—particularly in phosphorus compounds—might be attributable to an increase in intracellular potassium ions. The mechanism of this can only be determined by further experiment.

R. Fåhraeus (Sweden) described the "Tissue injury due to the reduced filtrability of the erythrocytes". The intravascular aggregation of the erythrocytes in rouleau formation (termed by Knisely 'sludging') implies a mechanism which is advantageous for the circulation of the blood in certain aspects of the vascular system. This aggregation of the erythrocytes favours their transport at the expense of the plasma and decreases the relative viscosity of the blood. But such rouleau formation may give rise to circulatory disturbance.

Determination of the filtrability of the erythrocytes at different blood pressures indicates that a large fall in blood pressure must have a more serious prognosis when the suspension of the blood is strongly reduced. In clinical cases with great aggregation of the erythrocytes the circulation *sub finem vitae* ceases earlier.

In reviewing the "Effect of physical injury on lipid metabolism", E. J. Masoro (United States) dealt mainly with the effects of cold injury and the interrelationship of energy generation and the intermediary metabolism of lipids. At the moment the greatest barrier to the understanding of the effect of physical injury on lipid metabolism is still the absence of certain key data.

D. P. Cuthbertson (Scotland) contributed by discussing "The disturbance of protein metabolism following physical injury". He pointed out that the increased metabolism and urinary excretion of nitrogen, sulphur, phosphorus, potassium and creatine are the main energy and material losses to the body following moderate to severe physical injury such as the fracture of a femur. These alterations in catabolism reach their peak about the third to eighth day in man. There is also generally a slight rise in body temperature and pulse-rate. Comparable changes in nitrogen metabolism are found in the rat, sheep and, as Needham has shown, even in Crustacea. This rise in the surviving organism succeeds an initial depression of vitality following receipt of the wound. In the animal depleted in protein there is no increase in protein catabolism and in heat production following injury. The degree of response is related to the previous nutritive state.

Injury to an animal leads to lessened activity and lessened activity usually results in a diminished food and water intake. The necessity to heal is urgent and Dr. Cuthbertson's view is that the injury done sets in motion a chain of events to meet both the exigencies of repair and of maintenance. This involves changes which may even affect the internal milieu. The rise in heat production which is traceable to the protein oxidized will undoubtedly affect the rates of biochemical reaction.

A. Pekkarinen (Finland) gave a well-documented account of "The effect of operation and physical injury on the adrenal glands and the vegetative nervous system in man". The excretion of adrenaline, noradrenaline and total 17-hydroxycorticosteroids increases markedly after certain operations, thus showing a close relation between the vegetative nervous system and the pituitary-adrenocortical system, at least functionally. The rises might be regarded as of therapeutic benefit, promoting the adaptation of the organism to the stress of operation. The highest urinary excretions of noradrenaline and adrenaline correspond to liberation of 5 mgm. noradrenaline and 8·4 mgm. adrenaline. In most patients the excretion of these substances becomes normal during the first three days after operation. It may also be assumed that the secretion of steroids by the suprarenal cortex may decrease owing to the increased circulatory 17-hydroxycorticosteroid inhibiting the secretion of adrenocorticotrophic hormones from the pituitary gland.

An interesting finding is the significantly higher excretion following injury of adrenaline, noradrenaline and total 17-hydroxycorticosteroids in men compared with women.

The part played by aldosterone secreted by the adrenal cortex in the regulation of the humoral equilibrium during operations is yet unknown.

"Fluid, electrolyte, and plasma protein disturbance in shock" were dealt with by R. C. Millican (United States). He pointed out that this kind of study is important, for circulatory collapse occurs in normal animals in which there are losses of fluid, electrolyte, and protein to the extent observed in shock arising from hæmorrhage or swelling at the site of physical injury. Under certain conditions death from shock can be prevented by administration of fluids, electrolytes, and proteins. In untreated shock associated with a swelling of the injured areas of about 4–5 per cent of body weight, the fluid accumulation within the injured area occurs at the expense of the injured tissues.

The total sodium accumulation in the injured area of mice following application of a tourniquet to the hind legs is equivalent to the entire sodium in the circulating blood, or approximately 25 per cent of the extracellular fluid.

Dr. Millican considered that as substantial amounts of potassium were liberated from injured tissues this was an important factor in shock when combined with the fluid and sodium loss. Doubt is cast on the importance of plasma protein in shock in mice by the lack of effectiveness of protein solutions when administered in the absence of electrolytes. Survival response is closely related to the sodium content of the administered fluid.

V. Wynn (England) took up one aspect of the clinical side in his paper on "Some problems of water metabolism following surgery". He considers that the common finding of a low plasma osmolarity for several days after the trauma is explained by water retention in excess of electrolytes. Since renal function may be otherwise normal, present evidence suggests persistent antidiuretic hormone secretion as the cause of the oliguria. It seems that the supraoptic-hypophyseal system is made more sensitive in some way by trauma, so that a variety of stimuli provoke secretion of antidiuretic hormone ; and the primary function of osmo-regulation by the system is seriously impeded or lost. An inhibitory effect upon aldosterone production is a secondary consequence of the water retention. This leads to renal loss and aggravates the hypotonicity of the body fluids.

In a discussion on the "Influence of environment on the metabolic response to injury" R. E. Haist (Canada) described his experiments, which indicate a prolongation of the survival time of rats, previously exposed to cold, and shocked by a clamping technique, over controls not so exposed. An increased blood volume due to the exposure may also be a factor. Sodium is retained by such cold-acclimatized animals. Previous cold-acclimatization does not alter the changes in muscle chemistry and temperature during and following ischæmia, or the hepatic blood flow after ischæmia, but does lead to a lesser hepatic temperature.

It was clear from H. Smith's (England) account of the "Biochemical response to bacterial injury" that infection with a number of bacteria and injection of different bacterial products can lead to a response in the host physiologically and biochemically similar to that produced by physical injury. The stimulus to this response appears to be a loss of circulating blood volume either from extravasation into tissue spaces locally or generally, for example, in shock produced by anthrax, or from a peripheral pooling of the blood and a decrease in venous return as, for example, in shock produced by staphylococcal and meningococcal toxins. The possible biochemical mechanisms whereby different bacterial products affect blood vessels is a relatively untouched field for research.

W. W. Spink (United States), in his paper on "Brucellosis as a model for metabolic studies on bacterial shock and inflammation," directed attention to the increasing interest shown in recent years in the peripheral vascular collapse caused by endotoxins of Gram-negative bacteria. There is vasoconstriction of the small vessels, which causes ischæmia of the tissues, and changes in cellular function result. This is followed by vasodilation and stagnation of blood, increased vascular permeability, and œdema and hæmorrhage. There is reduced cardiac output because of peripheral pooling of blood. Renal failure occurs because of the compensatory vasoconstriction, which results in ischæmic tubular necrosis.

The metabolic response of the host to bacterial invasion includes alterations in hormonal activity. The adrenal cortex is stimulated, as reflected by increased concentrations of adrenocorticoids, especially cortisone. The thyroid stimulates the activity of the adrenal cortex. Some doubt was expressed as to the wisdom of giving the large amounts of exogenous corticosteroids advised by Dr. Spink during the initial critical period of endotoxin shock. It was of interest that he had found that triiodothyronine accelerated the lethal action of endotoxin.

"The bacterial factor in traumatic shock" was discussed by J. Fine, E. D. Frank, H. A. Ravin, S. H. Rutenburg and F. B. Schweinburg (United States), who found evidence of a toxin appearing in the blood of animals in hæmorrhagic shock, such toxin having many of the hallmarks of a bacterial endotoxin. They consider that it is the cause of the irreversibility to transfusion in their standardized preparations. A toxin with similar properties to the one in the blood in hæmorrhagic shock is apparently present in the blood of the animal in tourniquet shock and in non-bacteræmic septic shock. The source of this toxin appears to be such Gram-negative bacteria as may be present in the animal's tissues, and the endotoxins normally present in the gastro-intestinal tract, which appear to enter the circulation at a steady rate, if only in trace quantities. It is thought that when shock, however produced, becomes unresponsive to therapy, the refractory state of the peripheral vessels is due to unneutralized endotoxins through impairment of the reticulo-endothelial system. The protective effect of reserpine and of dibenamine given prophylactically lend strength to the view that the endotoxins act adversely on these vessels by intensifying the local action of adrenaline or noradrenaline.

S. M. Rosenthal and H. Tabor (United States), in their paper on "Some aspects of therapy of injury", described the survival effects of administering isotonic sodium salts to mice subjected to what would otherwise be one lethal dose of burn trauma, tourniquet trauma or hæmorrhage. In their estimation, sodium and fluid depletion are the major factors in the cause of shock. Saline or plasma in amounts of 5 per cent of body-weight (50 ml./kgm.) is inadequate. These authors have been able to demonstrate a specific effect from the sodium ion in shock. Potassium salts behave in an opposite manner to sodium and are quite toxic. In shocked mice there is an eightfold increase over the toxicity in normal. Glucose and colloid solutions containing no sodium were relatively ineffective in the therapy of shock. The concept that plasma proteins exert their osmotic effects by being held rigidly in the vascular bed must be modified by the demonstration of Wasserman and Mayerson in 1952 that a complete extravascular circulation of the plasma proteins occurs every 20 hours.

In hæmorrhage and hæmorrhagic shock where there is a large loss of red cells, the striking efficacy of administering red cells has been clearly demonstrated, but there is little evidence to substantiate its value in shock from burn or other local trauma. In experimental burns and tourniquet shock whole blood is no more effective than plasma or saline solutions.

In studies on burned children in Peru a small but statistically significant benefit from plasma above that from saline was observed. The important problem of late deaths following severe burns is also being studied in Peru by Drs. Rosenthal and Millican.

This, the first main symposium covering this field of investigation to be held in Europe since the Second World War, was of great value to the participants. The papers contributed and the discussion which followed will be published in due course by Blackwell Scientific Publications, Ltd.

D. P. CUTHBERTSON

FREE RADICAL STABILIZATION

FREE radical chemistry began with the discovery of the stable aromatic free radicals by Gomberg in 1900. The second stage of the subject developed more gradually as the occurrence and importance of unstable free radicals became increasingly apparent and as kinetic and spectroscopic methods for their study in the gas phase and in solution were perfected. During the past few years a third chapter in free radical chemistry has been opened with the realization that even the most reactive of radicals can readily be stabilized for indefinite periods by trapping them in a rigid matrix at low temperatures.

An informal discussion of the Faraday Society on this subject was held in the Chemistry Department of the University of Sheffield on September 4 and 5. The meeting was attended by about one hundred and eighty scientists, half of whom were from Britain, fifty from the United States and Canada, and forty from other countries. Twenty-one papers, covering nearly all aspects of the subject, were presented and discussed.

The three principal methods of preparation of stabilized radicals are: (1) by irradiation of a rigid solid or solution at low temperatures; (2) by electrical or thermal dissociation of a gas and subsequent trapping on a cold surface; (3) by chemical reaction in a rigid or viscous medium, for example, polymerization.

The trapped radicals are then investigated by physical methods, the most useful being absorption spectroscopy in the infra-red, visible or ultra-violet regions, thermal analysis and electron paramagnetic resonance spectroscopy. The latter method is particularly appropriate, and it is fortunate that it was developed at about the same time as methods for the stabilization of radicals.

Practically every type of radical has now been stabilized by one of these methods, from atoms and diatomic radicals to complex odd-electron molecules in polymeric and biological systems. Although the subject is at an early stage of development, the identification of many of these radicals is now quite certain. The simplest of all—the hydrogen atom—is readily prepared and identified by means of its characteristic electron spin resonance doublet, and detailed studies of its formation by gamma irradiation of acid solutions at 77° K. were reported by R. Livingston, H. Zeldes, A. Weinberger and R. Holmberg (Oak Ridge National Laboratory). The isolation of other atomic species is less well established. Unstable products are undoubtedly present in the condensed products of an electrical discharge through nitrogen or after γ-irradiation or electron bombardment of the solid at 4° K. (E. M. Hörl, National Bureau of Standards, Washington), but the evidence at present suggests that, although nitrogen atoms have been detected, N_3 may be the main constituent under some conditions (L. A. Wall, D. W. Brown and R. E. Florin, National Bureau of Standards; also K. Jen, Johns Hopkins University, Maryland).

The first work on the stabilization of simple inorganic free radicals was that of F. O. Rice (Catholic University, Washington), who found a transient blue substance, attributed to the imine radical, in the condensed products of dissociation of NH_3. Rice illustrated this early experiment, as well as later work, by means of excellent colour films which he recommended as being more reliable than the actual experiment for demonstrations of this kind. G. Wilse Robinson and M. McCarty (Johns Hopkins University, Baltimore) reported some very interesting and successful work on the stabilization of diatomic and triatomic radicals at 4° K. The radicals NH, OH, CH, C_2, NH_2, HNO, HCO and CNO. prepared in the electrical discharge, have been positively identified in a rigid argon matrix by means of their electronic absorption spectra. The spectra are surprisingly sharp and reveal that radicals such as NH_2, NH and OH experience nearly free end-over-end rotation in the matrix.

Most successful work on the aliphatic radicals has utilized electron spin resonance methods since their electronic spectra lie in the far ultra-violet, and infra-red methods present many problems. For example, H. W. Brown (National Bureau of Standards) was not able to obtain the infra-red spectrum of methyl by photolysis of methyl iodide, but K. Jen successfully used this method to record its electron spin resonance spectrum. M. S. Matheson (Argonne National Laboratory) summarized the radicals which have so far been identified in the irradiation products of paraffins, alcohols, ethers, aldehydes, ketones, fatty acids and other aliphatic compounds. The electron spin resonance spectra of the simple alkyl radicals are now well established. The ethyl radical is formed by the γ-irradiation not only of ethane but also of ethylene, and R. Klein and M. D. Scheer (National Bureau of Standards) described studies of the reactions of hydrogen atoms with solid olefins at 77° K. which show that addition occurs readily under these conditions. The γ-irradiation of alcohols and ethers is very specific in removing almost exclusively the hydrogen atom from the carbon α to the oxygen. D. J. E. Ingram and M. C. R. Symons (University of Southampton) described how the same radicals are also formed by photolysis of a solution of hydrogen peroxide in the rigid alcohol; the OH radical first formed readily abstracts hydrogen from the alcohol at 77° K.

For the aromatic radicals electronic absorption spectroscopy has proved to be most useful. H. T. J. Chilton G. Porter (University of Sheffield) and E. E. Strachan (British Rayon Research Association) described the preparation and stabilization of a variety of such radicals both by photolysis and by gamma radiolysis of rigid solutions at 77° K. In the case of the ionizing radiations the dissociation of the aromatic molecules is brought about almost exclusively by transfer of energy absorbed by the solvent.

The irradiation of polymers leads to larger radicals, and these are often still present at normal temperatures. For example, V. V. Voevodsky (Academy of Sciences, U.S.S.R.) described electron spin resonance studies of radicals trapped in irradiated polytetrafluoroethylene at 77° K., some of which remain when the specimen is warmed to 20° C. Radicals are also trapped in polymers as a result of the polymerization reaction itself and are responsible for unusual and characteristic kinetic behaviour. C. E. H. Bawn, T. P. Hobin and W. J. McGarry (University of Liverpool) described studies of trapped radicals in acrylonitrile, vinyl chloride, styrene and vinylidene chloride.

The general occurrence of stabilized radicals in polymeric and biological systems was reviewed by C. H. Bamford and A. D. Jenkins (Courtaulds, Ltd., Maidenhead). Electron spin resonance measurements have shown that metabolically active plant and animal tissues such as leaves, roots, seeds, blood, muscle and liver have a remarkably high radical content, and W. Gordy (Duke University) described recent investigations on such systems. Their function and the means by which they are stabilized and, indeed, their chemical nature are little understood as yet. J. L. Vivo-Acrivos and M. S. Blois (Stanford University, California) reported on electron spin resonance studies of stable radicals in natural and synthetic melanins. D. K. Ghosh and D. H. Whiffen (University of Birmingham) described their detailed work on the electron spin resonance spectra of radicals trapped in a single crystal of glycine after gamma irradiation. It can be shown that the radical is $^{+}NH_3.CH.COO^{-}$. The spectrum is anisotropic and shows far more detail than that from a polycrystalline material. The arrangement of the trapped radicals has the same symmetry as that of the molecules in the host lattice.

Although the major effort in the field of radical stabilization is at present directed towards the identification of the trapped species, it is clear that, once the spectra have been assigned, the method will provide a powerful means of investigation in many fields, and particularly of the primary processes of photochemistry, radiation chemistry and the electrical discharge. Masterly reviews of these three aspects of the subject were given by H. Linschitz (Brandeis University), M. S. Matheson and H. P. Broida. There was considerable discussion of the characteristic behaviour of excited states in rigid media, and Broida stressed the need for more information about the matrix structure and about the fundamental limitations to trapped radical concentrations.

There has been a great deal of interest in the possible use of stabilized radicals as high-energy rocket propellants. The important quantity to be considered is the heat of reaction per gram, and there seems little hope of increasing this greatly above 3 kcal./gm. with conventional molecular fuels. If pure atomic hydrogen could be utilized, the heat of reaction would be 51·2 kcal./gm., but the present indications are that concentrations which can be trapped are limited to 1 per cent or less. Other, heavier radicals are all much less suitable, and G. C. Szego (General Electric Co., Cincinnati) concluded that, at present, this application of stabilized radicals is not promising. Some enthusiasm was shown about the possibility of utilizing metastable excited states, such as the triplet state of helium, which has an excess energy of 113 kcal./gm.

Special experimental techniques are mainly concerned with the adaptation of existing methods to low temperatures. L. J. Shoen, L. E. Kuentzel and H. P. Broida (National Bureau of Standards) described glass Dewar flasks for optical studies at low temperatures, P. Le Goff and L. P. Blanchard (University of Nancy) described a mass spectrometer with a low-temperature ionization chamber, and H. S. Peiser (National Bureau of Standards) gave an account of his very elegant X-ray crystallographic studies on low-temperature solids.

The enthusiasm of the discussions was typical of a field where new phenomena are found in nearly every experiment which is performed. The international character of the meeting was a very pleasant feature, and this was assisted by financial support from the United States Department of the Army through its European research office.

GEORGE PORTER

NEW POTENT REACTIVATORS OF ACETOCHOLINESTERASE INHIBITED BY TETRAETHYL PYROPHOSPHATE

By DR. F. HOBBIGER
Department of Pharmacology,
AND
DR. D. G. O'SULLIVAN and DR. P. W. SADLER
Courtauld Institute of Biochemistry,
Middlesex Hospital Medical School, London, W.1

CERTAIN organophosphates, for example, tetraethyl pyrophosphate (TEPP), di*iso*propyl phosphonofluoridate (DFP), diethyl *p*-nitrophenylphosphate (*E* 600), and a number of widely used insecticides and their metabolites, are potent inhibitors of acetocholinesterase. Organophosphate poisoning (fatal when sufficient acetylcholine has accumulated in the body) has been reported from many countries, especially from Japan[1] and the United States[2], and an efficient treatment has become essential. Acetocholinesterase is reputed to possess positively and negatively charged regions, commonly called anionic and esteratic sites, which participate in the hydrolysis of acetylcholine. In the inhibition process, a dialkylphosphoryl group, or some related group, becomes attached to the esteratic site and in this way deprives the enzyme of its hydrolytic function[3]. Spontaneous reactivation of diethyl phosphoryl-acetocholinesterase occurs very slowly, but the formation of di*iso*propyl phosphoryl-acetocholinesterase is, for all practical purposes, irreversible[4].

Certain nucleophilic reagents restore the activity of freshly phosphorylated acetocholinesterase by displacing the phosphoryl group from the enzyme[3]. Hitherto, pyridine-2-aldoxime methiodide has proved, in general, to be the most potent reactivator, and attachment of its quaternary nitrogen to the anionic site of the phosphorylated enzyme has been considered to contribute to its potency[5].

During the past two years we have synthesized a large number of oximes and studied the affinity of these compounds for acetocholinesterase, their interaction with tetraethyl pyrophosphate, and their effectiveness in restoring the activity of acetocholinesterase inhibited by tetraethyl pyrophosphate. The compounds can be classified roughly as aliphatic oximes, and compounds related to pyridine, indole, indolinene, quinoline and *iso*quinoline. The most powerful reactivators that have so far emerged are structurally related to pyridine, the effectiveness of some of these being shown in Tables 1 and 2. Monoximes and dioximes of *bis*-pyridinium ions (compounds 12–18; Table 2) are all considerably more potent reactivators than pyridine-2-aldoxime methiodide (*P*-2-*AM*) although they are derivatives of the less active pyridine-4-aldoxime methiodide (*P*-4-*AM*). A considerable gain in activity is also obtained by terminal halogen substitution in the alkyl side-chain (compare compounds 3 and 8). Table 2 shows that the reactivating power of the oximes cannot be predicted from their hydrolytic activity and their affinity for the anionic site of acetocholinesterase. The order of activities found :

$$P\text{-}2\text{-}AM > P\text{-}4\text{-}AM \gg P\text{-}3\text{-}AM$$

is in conformity with unpublished results obtained with other compounds, which suggests that a conjugative connexion between the quaternary nitrogen and an oxime or hydroxamic acid group is an essential feature for high activity.

All the compounds in Table 2 have been subjected to a preliminary screening for antidotal properties.

TABLE 1

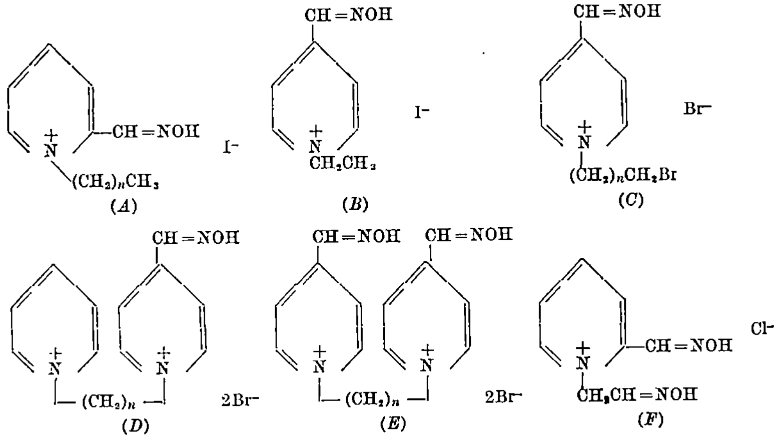

TABLE 2. *In vitro* REACTIVATION OF HUMAN ACETOCHOLINESTERASE INHIBITED BY TETRAETHYL PYROPHOSPHATE

No.	Oxime	Melting point (°C.)	*A* Potency as reactivator	*B* Calculated value for *A*	*C* Ratio $\frac{A}{B} \times 100$
1	*P*-2-*AM*	225	100	100	100
2	*P*-3-*AM*	156	0·03	11	0·27
3	*P*-4-*AM*	179	6	26	23
	(*A*)				
4	$n = 1$	180	54	210	26
5	$n = 2$	192	63	560	11
6	$n = 3$	168	87	6,780	1·3
7	(*B*)	152	3	18	17
	(*C*)				
8	$n = 0$	245	160	80	200
9	$n = 2$	165	190	750	25
10	$n = 3$	144	25	790	3·2
11	$n = 4$	164	94	160	58
	(*D*)				
12	$n = 3$	225d	800	42	1,900
13	$n = 4$	235d	670	21	3,200
14	$n = 5$	195	750	87	8,600
	(*E*)				
15	$n = 2$	310	1,700	110	1,500
16	$n = 3$	239d	2,200	95	2,400
17	$n = 4$	240d	1,800	100	1,800
18	$n = 5$	209d	1,600	740	210
19	(*F*)	196	20	220	9

Washed human red cells were used as enzyme source and results obtained with *P*-2-*AM* were taken as 100. *B* is the affinity of the oxime for acetocholinesterase × rate of interaction of the oxime with 2×10^{-3} *M* tetraethyl pyrophosphate. All experiments were carried out at 37° C. with 0·01 *M* acetylcholine chloride as substrate in a medium of 0·025 *M* sodium bicarbonate equilibrated with 95 per cent nitrogen + 5 per cent carbon dioxide. The method for determining *A* was in principle that described previously (ref. 9), except that reactivation was allowed to proceed in the centre of the manometric vessel for 30 min. before addition of the substrate.

Table 3. PROTECTION BY OXIMES AGAINST LETHAL TETRAETHYL PYROPHOSPHATE POISONING

Compound	No. of mice surviving for 24 hr./No. of mice injected					
	µgm. Tetraethyl pyrophosphate injected per mouse					
	8	16	32	64	128	256
—	5/6	0/8	0/6	0/6	0/6	0/6
P-2-*AM*	—	0/6	0/18	0/4	—	—
12	—	4/4	3/6	1/4	—	—
13	—	—	5/6	1/4	—	
14	—	—	5/6	4/4	3/5	0/5
15	—	4/4	2/6	1/4	—	—
16	—	—	6/6	4/4	5/5	7/15
17	—	—	6/6	4/4	4/5	0/5

Compounds were administered in amounts equimolar to 0·5 mgm. *P*-2-*AM* per mouse. Male white mice weighing between 18 and 20 gm. were injected intraperitoneally with 0·2 ml. of the oxime in 0·9 per cent sodium chloride solution and then 5 to 8 min. later they were injected subcutaneously with 0·2 ml. tetraethyl pyrophosphate in 0·9 per cent sodium chloride solution. Mice injected with the oximes alone showed no visible changes.

As can be seen from Table 3, under the experimental conditions chosen, some oximes and dioximes of *bis*-pyridinium ions are markedly superior to pyridine-2-aldoxime methiodide as antidotes to tetraethyl pyrophosphate *in vivo*. If tolerated satisfactorily, they will be considerably superior to pyridine-2-aldoxime methiodide in restoring the activity of acetocholinesterase in human beings poisoned by organophosphates. This is of great potential importance since most of the new compounds listed in Table 3 are more soluble and appear to be more stable than pyridine-2-aldoxime methiodide, and also in view of the reported observation that 1 gm. of the latter, injected intravenously, restores the activity of erythrocyte acetocholinesterase in human beings poisoned with parathion, but has only a disappointingly small influence on the phosphorylated enzyme formed by other organophosphates[6].

It might be expected that oximes of relatively low toxicity which, in relation to pyridine-2-aldoxime methiodide, have a higher affinity for acetocholinesterase or hydrolyse tetraethyl pyrophosphate more rapidly, would protect animals against lethal tetraethyl pyrophosphate poisoning to a greater extent than pyridine-2-aldoxime methiodide. Compounds 6, 9 and 10 have a 64-, 17- and 22-fold higher affinity than pyridine-2-aldoxime methiodide for acetocholinesterase, and compound 8 is 2·6 times more effective than pyridine-2-aldoxime methiodide in hydrolysing tetraethyl pyrophosphate. However, under the experimental conditions of Table 3, compounds 6, 8, 9 and 10 failed to protect mice from a lethal dose of 32 µgm. tetraethyl pyrophosphate.

A complete account of this work is to be published elsewhere. While this work was in progress, two reports[7,8] have appeared describing the reactivating and the antidotal effect of compound 16 in animals poisoned with sarin. Discrepancies between the findings of these authors and the results presented here probably arise from differences in the type of phosphorylated enzyme.

Should the results obtained with compound 16 be applicable to other species, pyridine-2-aldoxime methiodide becomes obsolete as an antidote for tetraethyl pyrophosphate poisoning. Since many of the insecticides used at present form diethylphosphoryl-acetocholinesterase, there is a good chance that compound 16 will be highly effective in many cases of accidental organophosphate poisoning which are frequently reported.

Two of us (D. G. O'S. and P. W. S.) wish to thank the Department of Scientific and Industrial Research for a special research grant that has defrayed some of the cost of this work.

ADRENALINE/NORADRENALINE RATIO IN THE ADRENAL GLANDS OF THE HEDGEHOG DURING SUMMER ACTIVITY AND HIBERNATION

By Prof. PAAVO SUOMALAINEN
Department of Histology and Physiology, Zoological Institute

AND

Dr. VEIKKO J. UUSPÄÄ
Department of Pharmacology,
University of Helsinki

WE have recently published figures for the adrenaline and noradrenaline content of the adrenal glands of the hedgehog during the summer[1]. The adrenal glands of the active hedgehog with a normal body temperature contain considerable amounts of noradrenaline, the values being 40 per cent of the total catechol amine content in the male, and rather less in the female. With regard to the adrenaline/noradrenaline ratio, the hedgehog belongs to the same type as the cat family.

In continuation of this study, we have determined the catechol amines in the adrenal glands of the hedgehog at other times of year, and especially during natural hibernation. The adrenaline and noradrenaline were separated by paper chromatography, eluted and determined biologically (chiefly by their effect on the blood pressure or colon of the rat). We have also made histochemical determinations by Hillarp–Hökfelt's reaction[2].

The average values of these biological determinations for the different seasons are presented in Table 1 and Fig. 1. From these it is seen that the adrenaline/noradrenaline ratio in the adrenal glands of the hedgehog changes towards the end of September, as the result of a fall in noradrenaline content. The hedgehogs are then still homoiothermic. At the end of November an investigation was made on two hedgehogs which had already entered into hibernation and become hypothermic. In the adrenals of one of these, the adrenal content had increased. In mid-winter, when the hedgehogs were in deep hibernation, the noradrenaline content of the adrenals was consistently very low, while simultaneously the value for adrenaline was usually found to be strikingly high. At this time the adrenal glands of the hedgehog resemble those of the rat with regard to the adrenaline/noradrenaline ratio. When the hedgehog had emerged from hibernation in the natural way in spring, the noradrenaline content of the adrenals had clearly increased and the adrenaline content again decreased. The noradrenaline content appears to increase in the early spring, while the hedgehog is still in the hibernating state. At this time the adrenaline content of the adrenals has not yet decreased.

For comparison, we have also estimated noradrenaline and total catechol amines histochemically by means of Hillarp–Hökfelt's reaction[2]. The depth of staining of the microscopic preparations has been measured photometrically with a photocell connected with the microscope tube. The values obtained are only roughly relative. The darker the preparation, the greater is the photocell index.

The average values of the photometric measurements are given in Table 2. It will be seen that the noradrenaline and total catechol amine contents change in the same way, broadly speaking, as in Fig. 1. The ratio of noradrenaline to total catechol amines cannot be estimated in this way.

The natural hibernation and hypothermy of the hedgehog is a cold stress. The general adaptation syndrome is already developed by autumn, however, before the hedgehog hibernates[3,4]. This condition is a clear alarm reaction. In adrenals investigated a couple of weeks before the onset of hibernation, the cortex had passed into the resistance stage of the adaptation syndrome. In hibernation, the resistance stage seemed to continue. The cortex appears to be particularly active in deep hibernation, for example, during periods of intense cold in mid-winter.

Table 1. ADRENALINE AND NORADRENALINE CONTENT OF THE ADRENAL GLANDS OF THE HEDGEHOG IN DIFFERENT SEASONS

Season	No. of animals	Body-weight (gm.)	Adrenal weight		Catechol amines				Condition
			Absolute weight (mgm.)	Relative weight (mgm./100 gm. body-weight)	Total (μgm./gm. adrenal weight)	Adrenaline (μgm./gm. adrenal weight)	Noradrenaline (μgm./gm. adrenal weight)	Noradrenaline per cent	
Early summer	5	560	389	69·5	320	199	121	37·8	Awake
Midsummer	6	650	305	46·9	493	338	155	31·4	
Autumn	4	458	253	55·2	387	332	55	15·0	
Early winter	2	378	231	61·1	587	526	61	10·4	Hibernating
Midwinter	9	498	239	48·0	617	585	32	5·2	
Early spring	3	385	218	56·6	713	576	137	19·2	
Spring	2	645	267	41·4	462	380	82	17·7	Awake

When hedgehogs were investigated in spring, after they had emerged from hibernation in Nature, the histological picture presented by the adrenals was rather different in different individuals. In some specimens the adrenals were evidently in a slight alarm reaction, whereas in others the cortex was slightly active. By the end of May or in the beginning of June, the function of the cortex seemed to have become normal.

It is believed that adrenocorticotrophic hormone is secreted in proportion to the momentary degree of bodily stress. Injections of adrenaline or sympathetic stimulation are known to cause an enormous increase in the production of adrenocorticotrophic hormone and adrenocorticoids. Consequently, it is believed that the reaction to stress is at least largely due to the fact that adrenaline has a direct or indirect effect on the anterior pituitary gland, increasing the secretion of adrenocorticotrophic hormone. Evidently the neurosecretion from the hypothalamus also participates in the activation of the anterior pituitary and the adrenal cortex[5].

As yet, we have not determined the adrenaline from the blood during hibernation. It is noteworthy, however, that the adrenaline content of the adrenals of the hedgehog usually increases just at the time when the cortex, too, is activated on account of physiological stress. This is especially the case during periods of intense cold in midwinter. But even in autumn, before the onset of hibernation, the ratio of adrenaline to noradrenaline has already increased. The high adrenaline content of the adrenals during hibernation fits in well with Selye's results, according to which "during the stage of resistance the adrenal medulla regains its chromaffinity"[6]. In spring, when the hedgehog emerges from hibernation and changes again from hypothermy to homoiothermy, the adrenaline content of the adrenals decreases greatly, as it usually does in a strong alarm reaction.

The question of what factors are responsible, despite the increase in the adrenaline content of the adrenals, for the various special features of the hedgehog's hibernation, such as the marked bradycardia, hypoglycæmia and steady glycogen content of the liver and muscles throughout hibernation[3,4], will be discussed elsewhere.

Table 2. RELATIVE PHOTOCELL INDICES FOR HISTOCHEMICAL DETERMINATIONS OF THE TOTAL CATECHOL AMINES AND NORADRENALINE IN THE ADRENAL GLANDS OF THE HEDGEHOG

	Total catechol amines	Noradrenaline
Summer	4·7	2·1
Autumn	4·4	1·3
Early winter	4·9	2·1
Midwinter	5·1	1·4
Early spring	4·9	1·1
Spring	4·6	1·6

In Table 1 attention is directed to the low noradrenaline content of the adrenals during the time of deep hibernation. At this stage of our experiments the physiological significance of this change cannot be explained. There is a dual physiological requirement of noradrenaline: (1) a local, intra-adrenal one as a metabolic precursor of adrenaline; and (2) a general, extra-adrenal one as a real independent hormone. The increase in the noradrenaline content of the adrenals in spring and summer might indicate at least an increased local need. Whether the notable decrease in the noradrenaline content of the adrenals during hibernation should then be taken to mean that its formation has decreased or that its extra-glandular requirement has increased is difficult to say before measurements have been made of the secretion of catechol amines into the blood in the different seasons of the hedgehog's activity. Hsieh and Carlson[7] have recently shown that noradrenaline had little effect in warm-adapted rats, but a marked calorigenic response in cold-adapted rats. Noradrenaline may thus play an important part in the chemical regulation of heat production in cold-adapted animals.

When the animal awakes from hibernation and becomes homoiothermic again, the rewarming of the anterior half of the body takes place much more rapidly than that of the posterior half[8,9]. Lyman and Chatfield have shown[9] that vasoconstriction takes place in the vessels of the posterior part of the body and in the intestines caudal to the liver. The blood then circulates only in the anterior part of the body. All the heat produced by the heart and the muscles of the anterior trunk serves to warm the front half of the body. What connexion may exist between the variation in the noradrenaline and adrenaline content, in addition to any other possible vasoconstrictory substances, and such changes in vasoconstriction and vasodilation is still unknown.

It seems to us obvious that the results presented above are in harmony with the view that the physiological production of the different catechol amines in the adrenal glands is controlled by separate hypothalamic centres[10].

HYPERCHROMICITY AND NUCLEIC ACIDS

By Dr. A. M. MICHELSON
Arthur Guinness, Son and Co. (Dublin), Ltd., Dublin, Ireland

DEGRADATION of ribonucleic acids by alkali, ribonucleases and other reagents, and of deoxyribonucleic acids on treatment with deoxyribonucleases or on denaturation, is accompanied by an increase in ultra-violet absorption, normally measured in the region of 260 mμ, the absorption maximum for nucleic acids. In view of the profound importance of the anomalous ultra-violet absorption characteristics of nucleic acids in relationship to the fine structure of the macromolecule, the hyperchromicity of a number of relatively simple polynucleotide derivatives was studied. It should, perhaps, be emphasized that, except as otherwise described, the specimens used were synthetic[1] and as such contained a mixture of 3′ : 5′ and 2′ : 5′ internucleotide linkages, in contrast to natural and biosynthetic polymers, which have 3′ : 5′ linkages exclusively. The results are given in Table 1. Contrary to statements in the literature[2] that hyperchromicity is not due to the simple union of a few mononucleotides, it can be seen that appreciable values are obtained even for dinucleotide derivatives, in agreement with the observations of Sinsheimer[3] and of de Garilhe and Laskowski[4] that small oligodeoxynucleotides have about a 10 per cent hyperchromic effect. Thus, even a simple dinucleoside phosphate—adenosine-2′ uridine-5′ phosphate[5]—exhibits a hyperchromicity of 12·8 per cent (as does the analogous adenosine-2′(3′) thymidine-5′ phosphate[6]), whereas in the polyadenylic series, hyperchromicity rapidly reaches a limiting value of approximately 35 per cent at chain lengths of 5–6.

In view of the zero hyperchromicity of polyguanylic acids at alkaline pH's, the variation of hypochromicity with pH was examined for a number of derivatives (Table 2). The results indicate that while ionization of the purine or pyrimidine moiety has a pronounced effect in certain cases, hydrogen bonding between the bases cannot be accepted as a cause of hyperchromicity in simple nucleotide derivatives.

Table 1

Compound	Average chain length	$\lambda_{max.}$ in 0·2 N sodium hydroxide		Alkaline hyper-chromicity
		Polymer (mμ)	Products (mμ)	
A 2′(3′)P	—	—	259·5	0
Diadenylic acid	—	258·5	259·5	15·1
Triadenylic acid	—	258	259·5	22·8
Tetraadenylic acid	—	258	259·5	30·7
Pentaadenylic acid	—	258	259·5	32·9

Table 2

Acid	Hyperchromicity		
	0·01 N hydrochloric acid	Water (pH 7)	0·2 N sodium hydroxide
Diadenylic	0	—	15·1
Triadenylic	6·8	—	22·8
Tetraadenylic	13·2	—	30·7
Pentaadenylic	16·4	—	32·9
Polyadenylic (13·6)	22·9	—	36·7
Polyguanylic (3·2)	9·0	10·3	0
Polyguanylic (5·4)	14·6	16·5	0
Polyguanylic (12·5)	18·0	23·0	0
Polyadenylicguanylic (6·2)	14·7	36·7	19·0
A2′P5′U	12·3	16·0	12·8

While the results for polyguanylic acid are possibly an extreme example of the variation of hyperchromic effect with pH, it is clear that the effect of pH on the ultra-violet absorption of a large nucleic acid, relative to that of its component mononucleotides, will be a composite of many different curves, characteristic not only of the nucleotide composition but also of the order of bases in the polymer. The hyperchromic effect on degradation of the polymer is likewise a function not of any particular tract of nucleotides but of the total molecule determined by both the composition and order of the various bases.

It may be noted that in addition to the reduction in ultra-violet absorption there is also a small hypsochromic shift accompanying polymer formation, as has been reported by Warner[7] for biosynthetic polymers of high molecular weight.

Pronounced changes in the apparent pK values of the bases have also been observed. While in biosynthetic polymers of high molecular weight this could be due to hydrogen bonding in a macromolecular structure, in the smaller synthetic materials this is unlikely. Thus, the apparent pK of 2·32 found for guanosine-2′(3′) phosphate is shifted to 2·63 for polyguanylic acid (average chain-length 5·4 nucleotides), while that at 9·33 shifts to 10·76 for polyguanylic acid with an average chain-length of 5·4 units and to 11·20 for polyguanylic acid (average chain-length 12·5), using spectrophotometric titration to estimate apparent pK (Fig. 1).

Since the ionizable groups participate directly in the electron system giving rise to the absorption, any perturbation of the π-electron system of the purine or pyrimidine ring will have an effect on such groups. It is therefore considered that the hypochromic effect observed on formation of polynucleotides is essentially due to the interaction of π-electrons of adjacent rings (cf. refs. 8 and 9), with the formation of electron orbitals extending over more than one unit, orientated normal to the planes of the ring systems stacked in layers above each other, forming essentially a new electronic species. While this interaction has an effect on the ionizable groups, it is clear that perturbation of these groups—by hydrogen bonding, or by ionization—will also have its effect on the total chromophoric system, without, however, breaking the π-bond interaction between the bases, which exists even at the dinucleotide-level and at all values of the pH. Variation in ionic strength, changing the macromolecular configuration and distribution of charge in the vicinity of the chromophore, will also have an effect on this interaction and hence on the ultra-violet absorption.

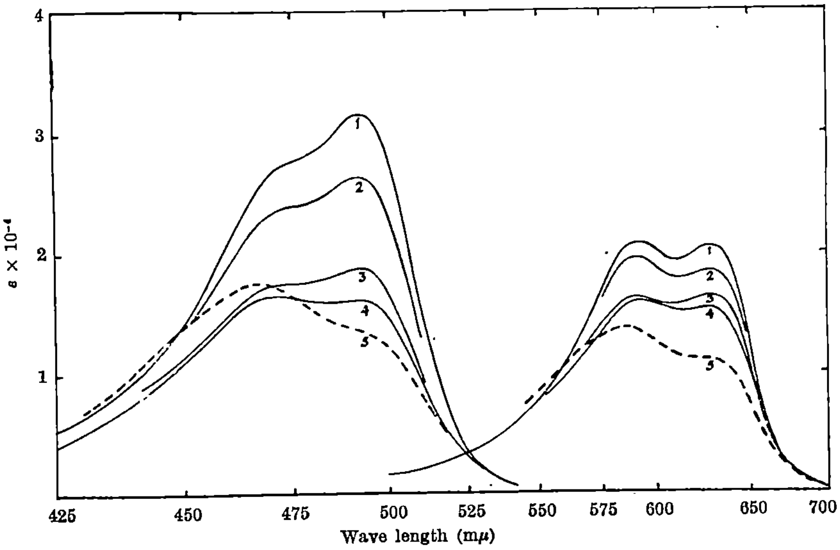

Fig. 2. Action of polynucleotides (3 × 10^{-5} M) on the absorption of acridine orange (3 × 10^{-5} M)—left; and toluidine blue (3 × 10^{-5} M)—right, in 0·01 M ammonium acetate at pH 6·8. 1, Dye alone; 2, 3, 4 and 5, with added polyuridylic acid, polyadenylic acid, polyguanylic acid and yeast ribonucleic acid, respectively

In view of the extensive work on the binding of various planar basic dyes and amino-acridines with nucleic acids, the effect of some low molecular weight synthetic polymers (average chain-length approximately 6) on the absorption spectra of rosaniline, toluidine blue and acridine orange was examined (Fig. 2). In all cases the effects due to the synthetic polymers were smaller than those observed with yeast nucleic acid. Since the linkages in the synthetic materials are mixed 2′–5′ and 3′–5′, the arrangement of phosphate groups along the backbone is not as uniform as in the natural material, so that while all sites may have been occupied, only where tracts of 2′–5′ or of 3′–5′ linkages occurred would any metachromasy result, giving rise effectively to 'dimeric' binding, rather than 'polymeric', using Lawley's[10] definition of the terms. Marked quenching of the fluorescence of acridine orange was also observed, particularly by polyguanylic acid and to a lesser extent by polyuridylic acid. Polyglycerophosphate[6] with an average chain-length of 12·1 glycerophosphate units was quite without effect on the absorption of these dyes or on the fluorescence of acridine orange, indicating the stereospecific requirements of the phosphate binding sites leading to induced metachromasy. That this induced metachromasy is a direct parallel to the similar effects observed in concentrated solutions of such dyes, and to the hypochromicity of polynucleotides, is further suggested by work which has shown that the forces operating between the rings of the neighbouring ions of dye aggregates have an equilibrium distance of 3–4 A.[11,12].

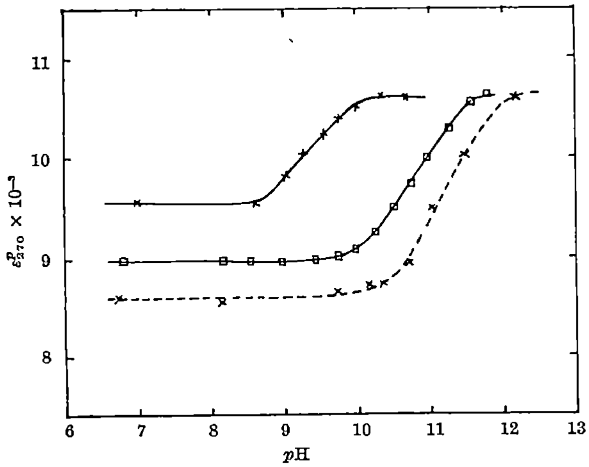

Fig. 1. Spectrophotometric titrations at 270 mμ of guanosine-2′(3′) phosphate —×—×—, polyguanylic acid (average chain-length 5·4) —☐—☐—, and polyguanylic acid (average chain-length 12·5) --×--×--

These three lines of evidence—the hyperchromic degradation of polymers, the corresponding hypochromic effect on the absorption of dyestuffs in combination with the polymer and the shift in apparent pK of the ionizable groups—point to a definite configuration for small polynucleotides and imply a restricted rotation about the internucleotide linkage even for dinucleotides. That the configuration favouring interplanar interaction may be of lower energy than other configurations has been shown by the effect of adenosine on the spectrum and fluorescence of riboflavin, particularly in flavin adenine dinucleotide[13].

Glucuronate Metabolism by *Aerobacter aerogenes*

THE initial reaction in the utilization of D-glucuronic acid by a number of bacterial species is catalysed by uronic isomerase[1-3]. The enzyme is constitutive in organisms that utilize glucuronate and induced in those organisms that become adapted to the utilization of glucuronate (refs. 2, 3 and unpublished work by Payne, W. J.).

The D-fructuronic acid formed by isomerase action may be converted afterwards to L-gulonic acid by a second enzyme, keturonic reductase, in the presence of reduced pyridine nucleotides, although reductase activity could not be demonstrated in all organisms studied[3]. The latter deficiency, and the fact that organisms adapted to uronate are not adapted to utilization of xylitol or the homologous aldo- or keto-pentoses expected from decarboxylation of gulonic acid, indicated that fructuronate might be metabolized by another pathway.

Table 1. PRODUCTS OF ANAEROBIC GLUCURONATE METABOLISM IN WHOLE CELLS

Anaerobic metabolism by	Δ Glucuronate (μmoles)	Δ Hydrogen (μmoles)	Δ Carbon dioxide (μmoles)	Δ Volatile acid (μmoles)
Aerobically adapted cells	− 1·0	0·0	0·0	+ 2·58
Anaerobically adapted cells	− 1·0	+ 1·95	+ 1·70	+ 2·04

Products of the anaerobic metabolism of glucuronate by cells of *Aerobacter aerogenes* adapted to glucurate utilization under aerobic and anaerobic conditions gave the stoichiometry shown in Table 1. These results suggested a cleavage to 3-carbon units according to the pathway:

$$\begin{aligned} &\text{glucuronate} \\ &\quad\rightleftharpoons \\ &\text{fructuronate} \rightarrow (2\ \text{pyruvate}) \rightarrow 2\ \text{acetate} + \\ &\qquad\qquad\qquad 2\ \text{formate} \rightarrow 2\text{H}_2 + 2\text{CO}_2 \end{aligned}$$

The inability of aerobically adapted cells to produce gas is caused by the failure of such cells to form the hydrogenlyase system necessary for formation of hydrogen and carbon dioxide from formate. The formation of volatile acid without production of carbon dioxide by aerobically adapted cells excludes the possible decarboxylation of gulonic acid as an intermediate step in the pathway.

Confirmation of the cleavage to 3-carbon compounds was obtained by use of extracts of cells grown anaerobically on glucose or glucuronate and ground with alumina. Aldolase activity could be measured with 2,4-dinitrophenylhydrazine according to the method proposed for the measurement of the cleavage of hexose diphosphate[5], since the *bis*-2,4-dinitrophenylhydrazones formed from the products of fructuronate cleavage gave similar colour reactions. Prior phosphorylation to fructuronate-1-phosphate by adenosine triphosphate was necessary for the cleavage reaction (Table 2).

A comparison of the enzymatic activities of cells grown with glucose and with glucuronate shows that the kinase and aldolase activities are the result of constitutive enzymes, probably non-specific reactions of fructose-6-phosphate kinase and hexose diphosphate aldolase. The specific activity of the induced uronic isomerase in the extracts is presented for comparison. The low activity of the kinase–aldolase system is apparently the rate-limiting reaction in the pathway, which thus accounts for the accumulation of fructuronate previously observed with dried cells[6]. Production of fructuronate-1-phosphate by the reverse reaction in the presence of dihydroxyacetone phosphate and tartronic semialdehyde can be measured with the cysteine–carbazole reaction[7]. No fructuronate was formed when dihydroxyacetone phosphate was replaced by dihydroxyacetone in the incubation mixture unless adenosine triphosphate and magnesium were also present.

Table 2. COMPARISON OF THE ENZYMATIC ACTIVITIES IN EXTRACTS OF CELLS GROWN IN GLUCOSE AND IN GLUCURONATE

Additions	Enzyme(s) measured	C_6 compound metabolized (μmoles/hr./mgm. of protein)	
		Extract of cells grown in glucose	Extract of cells grown in glucuronate
Glucuronate	Uronic isomerase	0·00	18·60
Hexose diphosphate	Aldolase	7·24	2·86
Fructose 6-phosphate	Kinase + aldolase	0·00	0·00
Fructose 6-phosphate + adenosine triphosphate + magnesium ions		2·20	1·85
Fructuronate		0·00	0·00
Fructuronate + adenosine triphosphate + magnesium ions		0·09	0·05

The products of aldolase action, dihydroxyacetone phosphate and tartronic semialdehyde, are afterwards metabolized to acetate, hydrogen and carbon dioxide by extracts of anaerobically adapted cells. The dihydroxyacetone phosphate fragment is metabolized to pyruvate by normal glycolytic enzymes with the production of reduced diphosphopyridine nucleotide at the level of triose phosphate dehydrogenase. The reduced diphosphopyridine nucleotide is re-oxidized by hydrogen transfer to tartronic semialdehyde to yield, presumably, glyceric acid in the presence of another induced enzyme, tartronic semialdehyde reductase, which can be readily measured by the change in optical density at 340 mμ (Table 3). Non-adapted cells contain small amounts of tartronic semialdehyde reductase activity that may be the result of non-specific aldehyde reductase activity in the crude extracts. Reversibility of the reductase reaction could not be measured in the presence of the very active reduced diphosphopyridine nucleotide oxidase in the extracts.

Table 3. TARTRONIC SEMIALDEHYDE REDUCTASE ACTIVITY OF CELL EXTRACTS

Extract of cells grown in:	Reduced diphosphopyridine nucleotide oxidized (μmole/hr./mgm. of protein)
Glucose	0·07
Glucuronate	0·57

Glyceric acid and 3-phosphoglyceric acid are metabolized to hydrogen and carbon dioxide by similar extracts. Preliminary results suggest that there is an initial phosphorylation by adenosine triphosphate prior to utilization of glycerate, but no glyceric acid kinase could be demonstrated in the crude extract by direct methods.

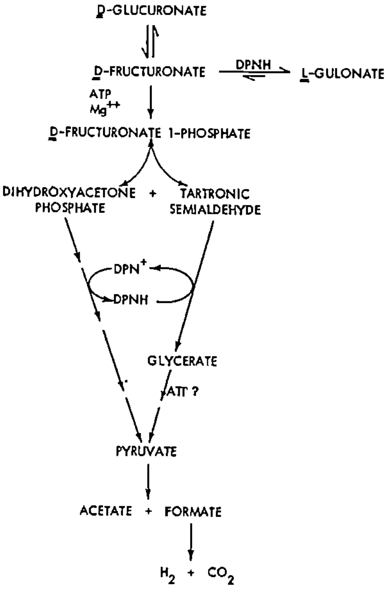

Fig. 1

Fig. 1 is a summary of the established reactions in the metabolism of glucuronate. The reactions leading to pyruvate probably represent the major pathway of glucuronate metabolism under aerobic as well as anaerobic conditions, since all the enzymes could also be demonstrated in extracts of aerobically grown cells.

Work is now in progress to isolate the enzymes from cells grown with glucose and with glucuronate, to determine the specificities of the induced and constitutive enzymes involved.

Calcium and Phosphorus Metabolism after Surgery

Clinically, the view is widely held that major surgical operations may encourage the growth of metastases in patients with certain types of cancer (stage III breast carcinoma, Wilm's tumour, bone and soft tissue sarcomas). It is possible that operative stress may favour the spread of tumours by affecting the adhesion between cells. In view of the known relation between lack of adhesiveness and low calcium content[1], an investigation of calcium and phosphorus metabolism in patients undergoing surgery has been undertaken.

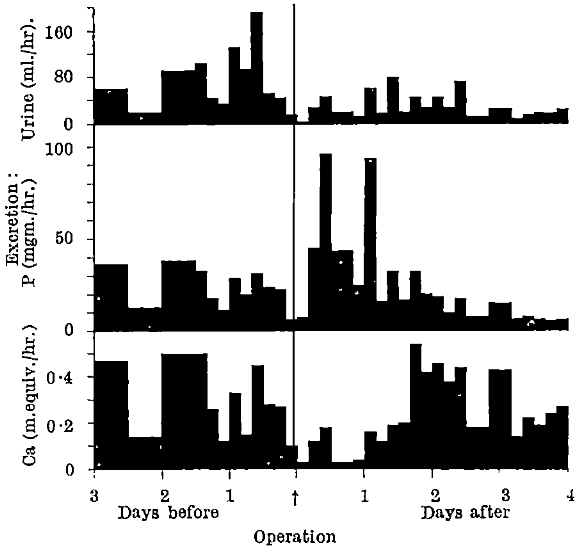

Fig. 1. The effect of a total hysterectomy (patient No. 246) on the urine, urinary phosphate and urinary calcium excretion rates

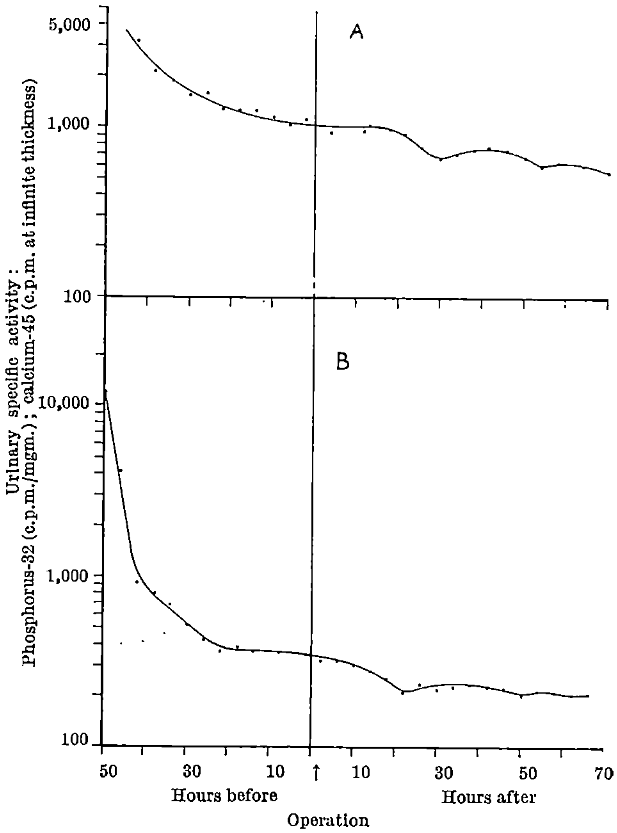

Fig. 2. *A*, The effect of a radical dissection of the inguinal lymph nodes (patient No. 611) on the specific activity of calcium-45 excreted in the urine (expressed as counts/min. of calcium oxalate at infinite thickness). *B*, The effect of an abdomino-perineal resection of the rectum (patient No. 486) on the specific activity of phosphorus-32 in the urine

Urinary excretion studies were carried out on 23 patients using four-hourly collection periods. Each collection has been analysed for calcium and inorganic phosphate and, in some cases, for total nitrogen, sodium, potassium, chloride and creatinine. Fig. 1 illustrates a calcium and phosphorus excretion pattern which has been found typical for uncomplicated major surgery. The phosphorus diuresis is a consistent finding and is usually observed to occur in association with retention of calcium.

Small doses of calcium-45 (14 µc.) and phosphorus-32 (20 µc.) have been administered parenterally to patients 48 hr. before surgery and the specific activity of the urinary calcium and phosphorus plotted against time[2]. In three out of eight patients studied, marked deviations from the expected calcium specific activity curve have been observed in the 48 hr. following operation (Fig. 2*A*). Two out of two phosphorus specific activity curves have shown a similar effect of operation (Fig. 2*B*).

It is suggested that the above observations are consistent with a post-operative calcium mobilization which, in most cases, could be associated with an increase in parathyroid activity. It could follow that surgical trauma produces a condition where there is a local or systemic demand by the tissues for calcium. This possibility, and the further speculation that changes in the calcium concentration of tissues may favour the spread and establishment of metastases, are at present being investigated.

We are indebted to the medical and nursing staff of the Special Unit for their generous co-operation.

Changes in the Sensitivity of Enzymes in the Dry State to Radiation

THERE is now considerable evidence that the sensitivity to radiation of enzymes in the dry state is influenced by the medium in which the enzymes are dried.

It was first noticed that different, commercially available invertase preparations had different radiation cross-sections in the dry state in a vacuum. This observation led us to prepare invertase solutions from commercial yeast using the purification methods described by Dieu[1], Fisher and Kohtes[2], and Sumner and O'Kane[3]. Although the enzyme solutions were prepared from the same yeast, the sensitivity of the enzyme showed variations even at different stages of purification. In Table 1 some of these results are given.

It can be seen that on dialysis of the Dieu extract the sensitivity of the enzyme increases considerably. If the dialysate from the dialysed extract of the Dieu preparation is added again to the residue, the cross-section returns to that of the crude extract. After free SH groups had been shown to be present in the yeast extract, cysteine and glutathione were tested for protective ability and were found to decrease the cross-section of several enzymes. Drying the enzyme from acetate buffer or from salt solutions in some cases led to greater sensitivity to radioactivity. In Table 2 the relative radiation sensitivities (for 4-MeV. deuterons) of four different enzymes dried down in solutions of various compounds are listed. In general, the effect of a compound on the radiosensitivity varied with its concentration. The results in Table 2 were obtained with a quantity of the added compound approximately one to ten times that of the enzyme used. Increasing the amount of compound added did not appear to change the values in Table 2 very much.

Table 1. INACTIVATION CROSS-SECTION (A.^{2}) OF DRY YEAST INVERTASE. 40 MeV. α-particles. Cross-section in yeast cell, 2,000 A.^{2}

Purification method	Dieu	Sumner	Fisher
Crude extract	1,350 ± 50	1,400 ± 100	2,400 ± 100
Dialysed extract	2,500		2,300
Precipitation	3,200		1,900
Final product		2,550	3,800

Table 2. RELATIVE RADIATION SENSITIVITIES OF ENZYMES IN THE DRY STATE

The conclusion to be drawn from these results is that the effect of ionizing radiation can either be increased or decreased. Reduction in radiation sensitivity of dry materials by added substances has recently been reported by Norman and Ginoza for catalase[4] and ribonucleic acid[5] and has been frequently observed in radiation studies on high polymers[6].

Further details will be reported elsewhere. This work was supported by a contract from the U.S. Atomic Energy Commission.

Radioprotective Action of 5-Hydroxytryptamine

TRYPTAMINE and its hydroxyl derivative are powerful radioprotective amines *in vivo*[1,2], but they also give rise to physiological changes. Bacq and Alexander[3] state that tryptamine is not a vasoconstrictor, but is nevertheless as good a radiation protector of mice as 5-hydroxytryptamine. However, tryptamine causes intense smooth muscle contraction, similar to its hydroxyl derivative[4,5]. While this pharmacological activity for tryptamine is much less, molecule for molecule[6], our studies indicate this also applies to its radioprotective properties in rats.

Both amines protect polymer irradiated in oxygenated solution *in vitro*[2], and Bacq and Alexander regard the protective action *in vivo* as one of competition for radicals (particularly HO_2) from radiolysis of water. Others[4] have suggested that protection *in vivo* may be due to an 'oxygen effect'.

Table 1. EFFECTS OF 5-HYDROXYTRYPTAMINE AND 5-HYDROXYTRYPTAMINE ANTAGONISTS ON LETHALITY, LOSS OF WEIGHT AND DIARRHŒA IN IRRADIATED RATS

Group* (Treatment)	No. of animals: mean weight (gm.)	No. of survivors (30 days)	Mean survival (days)	Weight loss, initial 10 days	Incidence of diarrhœa at fourth day (per cent)

* All injections given intraperitoneally; 5-hydroxytryptamine 5 min. before irradiation. For *d*-lysergic acid diethylamide, 1-benzyl-2-methyl-3-(2 aminoethyl) 5 methoxy indole hydrochloride (BAS-phenol) and BOL 148, single injections given 5 min. before irradiation, or 10 min. before irradiation were followed by 5-hydroxytryptamine.

† In experiments 1 and 2, Canberra Black stock rats were used in proportions of 2 males to 1 female for each group. In experiment 3 Wistar hooded female rats were used. All animals received 1,000 r. whole-body irradiation.

We have investigated the effect of pretreating rats with antagonists and specific anti-metabolites, preceding administration of 5-hydroxytryptamine and tryptamine, and its effect on acute lethality from total-body irradiation (1,000 r. X-rays). Results of some of these experiments are set out in Table 1, for the 5-hydroxytryptamine anti-metabolites, *d*-lysergic acid diethylamide (LSD), its brominated-derivative (BOL 148), and the anti-serotonin, 1-benzyl-2,5-dimethyl serotonin (BAS phenol)[6]. Acute lethality was assessed for a 30-day period following irradiation, as in previous experiments[7]. The loss of weight and incidence of diarrhœa in survivors was also charted.

Antagonists and anti-metabolites of 5-hydroxytryptamine alone had no significant protective action, but inhibited that of 5-hydroxytryptamine and tryptamine. Anti-histamines failed to influence the protective action of 5-hydroxytryptamine but the radioprotective action of histamine[8] was inhibited.

Atropine and dibenzyline, which respectively block two types of tryptamine receptors[9], in doses of 0·25 mgm. failed to influence the protective action of 5-hydroxytryptamine.

Tranquillization of rats with reserpine (20 mgm. per kgm.), 18 hr. before irradiation, did not influence lethality significantly. Given 5–10 min. before irradiation, a slight protection resulted which could be increased by pretreatment with iproniazid (100 mgm./kgm.) given 12 hr. before reserpine. However, administration of 5-hydroxytryptamine 5 min. before irradiation to reserpinized rats resulted in a radioprotective effect, comparable to 5-hydroxytryptamine alone in similar doses. Reserpine exerts a non-specific antagonism to 5-hydroxytryptamine and other amines in smooth-muscle preparations[10], and besides releasing and depleting these amines by a change from bound to free form, apparently reduces their capacity to react with cell receptors. An anti-metabolite (for example, 1-benzyl-2,5-dimethyl serotonin) is pictured as acting by excluding a structurally related metabolite (5-hydroxytryptamine) from combination with its normal specific reactant (5-hydroxytryptamine receptor)[11].

The results obtained point to a close correlation between the radioprotective action of certain amines *in vivo*, and their respective pharmacological actions. However, the narrow range of tissue oxygen tension, which governs the oxygen effect in radioprotection *in vivo*[12], seems an inadequate explanation for some of the results obtained, and in particular, the protection which results from the endogenous release of 5-hydroxytryptamine by combining reserpine with an amine oxidase inhibitor. The conception of radioprotection *in vivo* as largely one of competition for free radicals, also fails to afford a convincing explanation for the specificity of antimetabolites, in modifying the protective action of certain aromatic amines.

A full report will be published elsewhere. We thank Sandoz, Ltd., for liberal gifts of 5-hydroxytryptamine, lysergic acid diethylamide and BOL 148; Roche Products Pty., Ltd., for marsilid; and Merck and Co., Ltd., New York, for 1-benzyl-2,5-dimethyl serotonin, used in these experiments.

Liberation of Invertase from Disintegrated Yeast Cells

MYRBÄCK[1,2] found that if baker's yeast was treated with ethyl acetate for 20 hr. at room temperature and then thoroughly washed with water on the centrifuge a large proportion of its invertase activity remained in the insoluble fraction even when this was stored for several months at room temperature. It has long been known[3] that only a small fraction of the total invertase can be removed from yeast cells by simple extraction procedures, some form of autolysis being needed to liberate the remainder. Myrbäck suggested that treatment with ethyl acetate removes from the cell the enzymes responsible for the autolytic release of the invertase, which therefore remains indefinitely in combination with insoluble cell structures.

We have confirmed the effect of ethyl acetate treatment, but have obtained additional evidence which indicates, contrary to Myrbäck's view, that yeast invertase does not occur in an insoluble form.

In our experiments we used baker's yeast from a factory at Libán, Czechoslovakia. 150 gm. was kneaded with 15 ml. redistilled ethyl acetate; it liquefied, and was then shaken for 20 hr. at room temperature. After dilution to 1,500 ml. with distilled water the insoluble fraction was separated and washed repeatedly on the centrifuge, the final wash being colourless and virtually devoid of invertase activity. The precipitate was suspended in water to a total volume of 150 ml., and when plated on wort-agar showed no sign of living cells. It was preserved at room temperature with chloroform.

The total invertase content of each batch of yeast was assumed to be the sum of the activities of the final ethyl acetate-treated suspension and of the first supernatant, measured by a polarimetric method. All results are expressed in units per gm. original pressed yeast, one unit being that quantity of enzyme which inverts 1 mgm. sucrose/min. from a 5 per cent solution at pH 4·7 (0·02 M sodium acetate buffer) at room temperature (20–22° C.).

Experiments were made with suspensions freshly prepared, or at most 7 days old. During this period not more than 5 per cent of the invertase activity passed into the suspending fluid. Samples were centrifuged and the precipitates crushed in the Hughes press[4]. For example, 10 ml. of a suspension was centrifuged (1,000g) on the day it was prepared and a known fraction of the precipitate transferred to the Hughes press, crushed at −30° C., and washed off the block and re-suspended with water so that 1 ml. corresponded to 0·5 gm. of original yeast. On centrifugation for 1 hr. at 35,000g a slightly opalescent supernatant was obtained. Its invertase activity was 57 units, compared with 65 units for the suspension before crushing and an estimate of 72 units in the original yeast.

This result suggests that the invertase in the intact yeast cell is enclosed by membranes which are not permeable to it, and which are not sufficiently damaged by ethyl acetate treatment to allow it to escape. It is conceivable that one of the membranes concerned is the glucan layer of the cell wall[5]. Treatment with crop juice of *Helix pomatia*[6], which is known to attack this glucan[7], at a final dilution of 1 : 10, liberated practically all the invertase (125 out of 130 units) from a sample of ethyl acetate-treated material in 8 hr. at 20° C. It has been suggested that invertase must lie near the surface of the yeast cell[3], and so it is possible that it lies between the glucan layer and a protein-containing layer[5]. This might explain the liberation of invertase by the action of papain[1].

It is unlikely that invertase is solubilized by autolytic processes during the ethyl acetate treatment, because the crushing of washed samples of living baker's yeast liberates a large proportion of the invertase in a water-soluble form. Further, on treatment with 0·1 volume of undiluted snail crop juice at room temperature some 50 per cent of the invertase of a sample of living yeast was liberated in 10 hr., while at least 90 per cent of the cells remained viable.

The preparations treated with ethyl acetate retain the outward shape of yeast cells but have obviously lost a great deal of their contents. After crushing, many of the cells show gross destruction, and, on prolonged treatment with snail digestive juice, holes appear in the cell walls. However, it would seem that often quite minor damage is sufficient to set the invertase free. Myrbäck's ethyl acetate-treated preparations might therefore provide a useful and sensitive system for the investigation of the nature of the yeast cell wall.

Critical Effect of Oxygen Tension on Rate of Growth of Animal Cells in Continuous Suspended Culture

ITS relevance to current animal virus and cell culture work prompts us to report the feasibility of and requirements for continuous culture of cells in suspension; full details will be given elsewhere.

Medium was pumped at a known rate from a reservoir to a culture vessel kept at 37° C. (20-l. 'Pyrex' aspirators), which overflowed at a constant level into a cooled receiver and was harvested once weekly. Culture vessel and receiver were gassed with mixed carbon dioxide, oxygen and nitrogen and magnetically stirred. Mechanical reliability was essential, as small breakdowns were rapidly lethal. The medium, a modified Earle's saline plus lactalbumen hydrolysate, amino-acids, yeast extract, vitamins, horse and calf serum, contained most components at their highest non-toxic level; these levels are probably not vital for continuous culture except for glucose (6–8 gm./l.). The limiting cell-density was probably not reached, but growth was very rapid under optimal conditions (defined below). Varying the gas-phase carbon dioxide and including bicarbonate kept the pH neutral; a transformed embryo rabbit kidney cell line[1] was used. The system was not self-balancing (not a 'chemostat'), as limitation of medium did not much restrict growth without inducing a sometimes irreversible lag. Since 'steady state' therefore rarely occurred and since synchrony was also possible, growth-rates were not known precisely; they were recorded as 'percentage increase/24 hr.', based on the culture vessel content of a given day. Cells were counted and medium flow-rate, gas-phase carbon dioxide and oxygen levels adjusted daily to control *p*H, cell density and growth-rate. Medium changes were not needed, flow-rate being generally matched with growth-rate; carbon dioxide was 2–5 per cent and oxygen was 5–24 per cent (v/v), cell-density was 5–20 × 10^5 ml., and *p*H was roughly 6·9–7·2.

This system produced in four months continuous medium flow an average of 10^9 (2 gm. wet weight) cells/day in 1 l. of medium from a constant culture volume of 1·5 l. (Fig. 1). The mean doubling time was 25 hr., and sometimes 16 hr. or less. Continuous growth was more efficient and less troublesome than batch culture, in which the narrow optimal ranges of animal cells were soon exceeded. The cells were used for agar-suspension plaque assay[2] and suspension growth of polioviruses, making 10^{11} to 10^{12} plaque-forming units per week.

Unexpectedly, cell growth-rate was very dependent on oxygen levels. The gas mixtures bathing tissue cultures have hitherto had little attention, air (20 per cent v/v oxygen) or 5 per cent carbon dioxide-in-air (19 per cent oxygen) generally sufficing. We find that 20 per cent oxygen and above is relatively inhibitory, and once during a steady state a small drop (from 19 to 17 per cent oxygen) increased the growth-rate by 50 per cent. On another similar occasion, a small increase (from 22 to 24 per cent) halved the growth-rate, while in other experiments 25–30 per cent oxygen was rapidly cytocidal. Since the important factor is the liquid-phase oxygen level or equivalent redox potential, the gas-phase oxygen level for optimal growth at high cell density depends on rates of agitation, oxygen exchange across the surface and oxygen uptake/cell, surface area and depth of culture and cell density. Thus apparent doubling times were 24 hr. or less with oxygen-levels from 14 to 22 per cent (other conditions being constant), but cell densities allowing such optimal growth were always higher at higher oxygen-levels (Table 1). Growth-rates and cell densities were cyclic (Fig. 1). Starting with slight excess of oxygen, a slight rise in cell density decreased liquid-phase oxygen-levels, and growth-rate rose. Cell density also rose, presumably passing through optimal to hypoxic levels of oxygen, when the *p*H fell and growth almost stopped; this resembled a lag, as optimal conditions did not at once restore growth-rate.

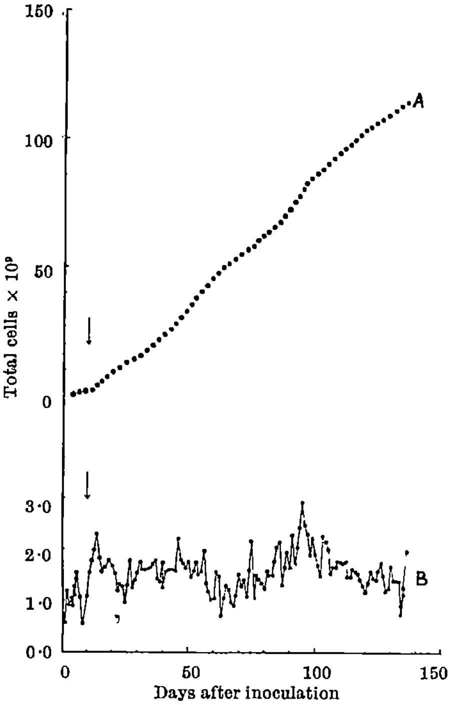

Fig. 1. Continuous growth of animal cells in suspension: *A*, cumulative production; *B*, culture vessel content. The medium was not varied and *p*H was 6·9–7·2; oxygen levels were often varied. Arrows indicate time when continuous flow started

Table 1. MEAN GAS-PHASE OXYGEN AND CULTURE-VESSEL CELL DENSITIES (SEE FIG. 1) WHEN THE CELL INCREASE/24 HR. EXCEEDED 87 PER CENT (PROBABLE MEAN DOUBLING TIMES OF 24 HR. OR LESS)

Percentage oxygen	14	16	16·5	17	18	20	22
Cells/ml. × 10^5	7·8	8·3	10·0	11·3	12·6	13·4	18·0

We conclude that liquid-phase oxygen-levels for fastest growth of these cells is much less than air (and even 14 per cent oxygen) equilibrium values; this has interesting implications for the usual stationary cultures.

Effect of Oxytocin Administration on Respiration of Lactating Mammary Gland Tissues in Rats

THE participation of the hypothalamus and the posterior lobe of the pituitary in milk ejection is well known. On the other hand, the importance of the suckling stimulus in maintaining the secretion of milk[1], suggested that the hypothalamus and the posterior lobe of the pituitary played some part in controlling the secretion of anterior pituitary galactopoietic hormones.

Recently, Benson and Folley[2] reported that the administration of oxytocin to a lactating rat retarded the mammary involution which occurred after weaning, and suggested the possible part which oxytocin plays in the release of prolactin and other lactogenic and galactopoietic hormones from the anterior pituitary gland. Since Benson and Folley obtained their results by a histological method and discussed the problem from this point of view, it is of interest to use a biochemical method for comparison. Therefore, as an indicator of the activity of the gland, the respiration and rate of production of lactic acid by the tissue slices were employed. The following experiments were carried out:

Table 1. EFFECTS OF OXYTOCIN ADMINISTRATION ON RESPIRATION AND LACTIC ACID PRODUCTION OF RAT MAMMARY GLAND TISSUES

Group	Respiratory quotient	$Q(O_2)$ (μl./mgm. dry wt. of tissue/hr.	Lactic acid produced (μgm./mgm. dry wt. of tissue/hr.)
Oxytocin 1·0 I.U. treated	(*a*) 0·92±0·04* (5)	7·15±3·66 (5)	6·71±4·06 (5)
Oxytocin 2·0 I.U. treated	(*b*) 0·92±0·05 (4)	7·08±3·03 (4)	4·97±2·57 (3)
Intact weaning control	(*c*) 0·94±0·03 (6)	6·11±1·17 (6)	5·58±2·26 (6)
Normal control	(*d*) 1·32±0·09 (4)	14·81±3·46 (4)	2·41±0·34 (3)

Figures in parenthesis represent the number of animals. * 95 per cent fiducial limits. *a* and *b* are not significantly different from *c* ($P < 0·01$); *a*, *b* and *c* are significantly different from *d* ($P > 0·2$).

Nineteen Wistar strain female rats in the first lactation, weighing 160–190 gm., were used. Litters were reduced to six on the first day of lactation, three of each sex being kept whenever possible. They were weaned on the twelfth day of lactation. Oxytocin (1·0 and 2·0 I.U. 'Pituitan': Dainippon Zoki Lab., Osaka) diluted in 0·5 ml. of distilled water, was injected intraperitoneally to nine mothers three times a day, beginning on the afternoon of the weaning day. 3 days after weaning (fifteenth day of lactation and 30 min. after the last injection), the animals were killed by decapitation. Six rats kept intact for 3 days after weaning, which occurred on the twelfth day of lactation (intact weaning control), and four rats on the fifteenth day of lactation (normal control), were used as controls.

The respiratory quotient and oxygen consumption of tissue slices from the mammary glands of these animals were measured manometrically with special flasks[3]. Incubations were carried out in a Krebs–Ringer phosphate solution (*p*H 7·4) containing 0·3 per cent glucose, with a 100 per cent oxygen gas phase—for 2 hr. at 37° C. The amount of lactic acid in the medium was determined chemically[4] after the incubation, and was expressed in terms of μgm./hr./mgm. final dry weight of the slices.

A steep decrease in the respiratory quotient and $-Q(O_2)$ value resulted from the weaning, the normal control tissue slices retaining high values. The rate of production of lactic acid increased after weaning, but remained low in the normal controls. These changes were not affected by oxytocin (Table 1). Vaginal cornification was observed within 2 or 3 days after weaning in both the oxytocin-treated and intact weaning control groups.

During the experimental period (3 days), the alveoli of the mammary glands of both the oxytocin-treated groups and the weaning control group were abundantly filled with milk, and histologically there was no evidence of involution. This observation was consistent with that of Benson and Folley[2] for the mammary gland 6 days after weaning.

The diminution of the respiratory quotient and the recurrence of œstrus may indicate the ineffectiveness of oxytocin on the galactopoiesis of mammary glands and on the maintenance of luteal activity in the ovaries. (This activity of oxytocin was reported by Desclin[5].) Nevertheless, we must take into consideration the results of Cross and Silver[6], who pointed out the importance of engorgement as a cause of the involution taking place after weaning. This suggests that, even if oxytocin has a galactopoietic effect, engorgement may overcome it.

In order to determine the essential role of oxytocin in galactopoiesis, the effects of engorgement of the mammary gland must be eliminated. The experiment, furthermore, must be carried out under conditions which suppress the suckling stimuli completely, since these stimuli are considered to reach the hypothalamus and to cause not only the release of oxytocin from the posterior lobe of pituitary, but also that of the galactopoietic hormones from the anterior lobe. Studies on this problem are now in progress.

After this communication had been sent to *Nature*, we were informed by Dr. A. T. Cowie, of the National Institute for Research in Dairying, Reading, England, that similar results had been obtained independently by Dr. M. L. McNaught[7]. She reported that, in rats, no significant differences in the respiratory activity *in vitro* of mammary gland slices were found between a group receiving 1 I.U. of oxytocin during the 12 hr. after removal of the litter, and a group receiving no oxytocin. She also discussed the effect of accumulation of milk.

Diuretic Activity of Chlorothiazide Derivatives

CHLOROTHIAZIDE (6-chloro-7-sulphamyl-1,2,4-benzothiadiazine-1,1-dioxide) is not only a very active diuretic drug, but it can also relieve high blood pressure in many patients. This compound has an inhibitory action on carbonic anhydrase, like N-acetylamino-sulphamyl-thiadiazole, and in addition it causes a diuresis not unlike that observed with organic mercurial compounds[1,2], resulting in increased excretion of sodium salts and of water. It seemed interesting to us to analyse the structural conditions necessary for a diuretic activity and, especially, what influence can be attributed to the sulphamyl-group.

1,2,4-benzothiadiazine-1,1-dioxide (Table 1, *a*) has no diuretic activity. The introduction of a sulphamyl-group (Table 1, *b*) gives barely active compound. Therefore, the activity is not mainly due to the sulphamyl-group. Further, ring-closure to thiadiazindioxide is not necessary for diuretic activity, since it is known[3] that 4-amino-6-chlorobenzene-1,3-disulphonamide and its N-acyl-compounds have a high activity.

We found that chlorine cannot be omitted in these compounds (Table 1, *c*), and that it cannot be replaced by an amino-group (Table 1, *d*). Substitution of the sulphamyl-group by alkylation should result in an inactive compound, since this group is responsible for the anti-enzymic effect. It is known[4] that N-alkyl-chlorothiazides have no diuretic activity, but to our great surprise we found a highly active and considerably less toxic compound in 4-amino-6-

Table 1

	Compound	Melting point (deg. C.)	Activity*
a	1,2,4-benzothiadiazine-1,1-dioxide	219–220	1·46

* Activity: $\frac{\text{Urinary excretion of treated animals}}{\text{Urinary excretion of untreated animals}}$ (ref. 5)

chloro-benzene-1,3-disulphonmethylamide (Table 1, *e*). Therefore, a free sulphonamide group is definitely not necessary for diuretic activity.

Activity decreases rapidly with increasing molecular weight of the alkyl-group (Table 1, *f* and *g*). The dimethyl compound (Table 1, *h*) still has activity and the morpholine compound slight activity, but the cyclohexyl-compound (Table 1, *i* and *j*) is inactive.

Further particulars, especially the pharmacological properties of the compound of Table 1, *e* will be described elsewhere.

Lipolysis in the Rumen

REISER[1], and more recently Shorland *et al.*[2], reported experiments in which rumen contents of sheep were incubated *in vitro* with linseed oil and with oleic, linoleic and linolenic acids. These experiments, and others using the living animal[3–5], demonstrated that hydrogenation of double bonds of unsaturated fatty acids occurred and that this was effected by the rumen micro-organisms.

We have done experiments in which triglycerides in the form of linseed oil and tung oil were incubated with the rumen contents of sheep (1·0 gm. per 100 ml. rumen contents) in a manner similar to that described by Shorland *et al.*[2]. Not only did hydrogenation occur as indicated by a considerable fall in the iodine value of the lipid, but it was also found that more than 75 per cent of the total lipid recovered at the end of the incubation was in the form of free higher fatty acids. In 'blanks' to which no oil was added, free higher fatty acids represented 50–60 per cent of the total lipid present. Rumen contents obtained from animals fed on rations containing hay and either potato starch and mixed concentrates (including fish meal) or flaked maize, maize meal, groundnut meal and oats gave similar results.

That the lipolysis is the result of enzyme action was demonstrated by incubating linseed oil (iodine value, 181·3) with rumen contents obtained from a fistulated sheep 4 hr. after the last feed of hay and mixed concentrates and with the same rumen contents which had been previously heated in a boiling water-bath. The results of one such experiment are given in Table 1. After allowing for the difference between the amounts of free fatty acids in flasks 2 and 4, it is calculated that about 60 per cent of the esterified fatty acid residues were liberated from the oil in flask 2. No lipolysis was observed in flask 4, the slight difference between the amounts of fatty acids recovered from flasks 3 and 4 being due to the traces of free acid originally present in the linseed oil. Noteworthy is the low iodine value of the fatty acids derived from rumen contents alone; calculation gives the iodine value of the acids resulting from lipolysis in flask 2 as 121·4, which represents a decrease of about 70 units compared with the iodine value of the acids present initially in glyceride combination.

Table 1. AMOUNTS AND IODINE VALUES OF FREE HIGHER FATTY ACIDS FOUND AFTER INCUBATING SHEEP RUMEN CONTENTS, WITH AND WITHOUT THE ADDITION OF LINSEED OIL, AT 37° C. FOR 24 HR. (Each flask contained 100 ml. rumen contents)

Flask	Treatment before incubation	Addition	Free fatty acids	
			Weight (mgm.)	Iodine value
1	None.	None	245	22·8
2	None	Linseed oil (1·00 gm.)	859	97·4
3	Heated at 90° C. for 1 hr.	None	236	31·6
4	Heated at 90° C. for 1 hr.	Linseed oil (1·00 gm.)	268	44·7

Extensive lipolysis of ingested glycerides in the rumen of the intact animal was found on examination of the contents of the alimentary tract of a sheep which had been fed for several months on a diet consisting largely of hay, linseed meal and maize to which 40 gm. of linseed oil were added daily. At slaughter, 7 hr. after the last feed, 80–90 per cent of the lipid in the rumen, abomasum and upper part of the small intestine was in the form of free higher fatty acids of iodine value about 70. In the lower part of the small intestine the free fatty acids comprised 68 per cent of the total lipids and had an iodine value of 48.

Saliva is one of the main constituents of the liquid phase of rumen contents, but no lipolytic activity towards linseed oil could be demonstrated in samples of adult sheep saliva which were made available to us by our colleague Dr. R. N. B. Kay. It is therefore presumed that micro-organisms are responsible for the production of a lipase in the rumen; in this connexion it is of interest to note that Johns[6] has already shown that glycerol is fermented slowly in the sheep's rumen to yield propionic acid.

Our preliminary observations indicate that, in the ruminant, dietary triglycerides reach the small intestine largely in the form of free fatty acids, of which the unsaturated components have been modified by hydrogenation. This is in marked contrast to the digestion of lipids in adult monogastric animals in which little or no lipolysis occurs before triglycerides of long-chain fatty acids reach the intestine

Further studies, both biochemical and bacteriological, on the fate of ingested lipids in the alimentary tract of ruminant animals are in progress.

Metabolism of 16-Oxoœstrone by Human Liver Slices *in vitro*

Layne and Marrian[1] recently reported the isolation of 16β-hydroxyœstrone from the urine of pregnant women, and Brown, Fishman and Gallagher[2] detected the same compound by reverse isotope dilution in the urine of a human subject after the administration of œstradiol-17β-16^{14}-C. In the course of our own studies on the metabolism of œstrogens *in vitro*, 16β-hydroxyœstrone has been found after incubation of 16-oxoœstrone with normal human liver slices. In addition, five other phenolic steroids have been identified as metabolites of 16-oxoœstrone.

In a typical experiment, 200 mgm. of liver slices were incubated with 100 μgm. of 16-oxoœstrone in 5 ml. Krebs phosphate saline for 60 min. at 37° C. The incubation medium and the tissue were extracted twice with equal volumes of an ether-chloroform mixture (3 : 1 v/v). In order to separate 16-oxoœstrone from the higher polar transformation products, the extracts were subjected to paper chromatography in the system benzene/methanol/water (100 : 55 : 45). The material more polar than 16-oxoœstrone was eluted and resubjected to chromatography in the system formamide/chloroform. After spraying the paper with Folin and Ciocalteu's reagent[3] eight substances (I–VIII) were detected, six of which had the same mobility and showed the same absorption curves in the Kober reaction as pure œstriol (II), 16-epi-œstriol (IV), 17-epi-œstriol (V), 16β-hydroxyœstrone (VI), 16-oxo-œstradiol-17β (VII) and 16α-hydroxyœstrone (VIII). For further identification, the metabolites were coupled with fast black salt *K* to make azo derivatives, followed by paper chromatography in the system toluene/petroleum ether/ethanol/water (200 : 100 : 30 : 70)[4]. With substances II and IV–VIII well-defined spots were formed, identical in all ways with spots produced by parallel runs of (R_F values in brackets) œstriol (0·07), 16-epi-œstriol (0·46), 17-epi-œstriol (0·32), 16β-hydroxyœstrone (0·56), 16-oxoœstradiol-17β (0·77) and 16α-hydroxyœstrone (0·60), respectively. In the sulphuric acid/water reaction[5] the absorption spectra of substances II, IV, V, VII and VIII were identical with those of (maxima in brackets) œstriol (282 ; 458 mμ), 16-epi-œstriol (290 ; 457 mμ), 17-epi-œstriol (286; 456 mμ), 16-oxoœstradiol-17β (272 ; 503 mμ) and 16α-hydroxyœstrone (270 ; 507 mμ) respectively. When substance VI was reduced with sodium borohydride, a compound was formed which was in every respect indistinguishable from 16-epi-œstriol. Since on reduction of authentic 16β-hydroxyœstrone with sodium borohydride only 16-epi-œstriol is formed while 16-oxoœstradiol-17β is reduced to 16-epi-œstrol as well as œstriol, it is concluded that substance VI is identical with 16β-hydroxyœstrone.

The quantitative examination of the extracts revealed that 16-oxoœstrone was metabolized very rapidly by human liver slices. The main metabolites were 16-oxoœstradiol-17β and 16β-hydroxyœstrone, whereas œstriol and 16-epi-œstriol were formed in smaller amounts. 16α-Hydroxyœstrone and 17-epi-œstriol were minor metabolites. It is interesting that we failed to detect any of the 16- or 17-hydroxy ring *D* ketols after incubation of œstriol, 16-epi-œstriol or 17-epi-œstriol with human liver. These findings and the experiments reported here support the view that the hydroxy ring *D* ketols are mainly derived either from direct hydroxylation[6] or, less probably, from oxidation and subsequent reduction[7] of œstrone rather than from oxidation of the corresponding triols. This concept, however, does not exclude the possibility that, to a small extent (less than 1 per cent), the triols can be oxidized to ring *D* ketols, as has recently be shown by Levitz, Spitzer and Twombly[8].

Full details will be published elsewhere. This investigation was supported in part by research grants from the Government of Nordrhein-Westfalen.

Pregnanediol in the Urine of the Ewe

The establishment of the relationship between progesterone and 5β-pregnane-3α : 20α-diol by Venning[1] was followed by a number of reports of the isolation of pregnanediol from the urine of other species.

Marker[2] reported that considerable quantities of pregnanediols were present in the urine of pregnant cows, bulls and steers, but Stevenson[3] and Hill[4] were unable to substantiate these findings.

Aparici[5] claimed to have measured large quantities of pregnanediol in the urine of pregnant cows but he did not isolate and characterize the material which he measured. In a recent comprehensive study of the lipid fraction of pregnant cow urine, Klyne and Wright[6] failed to identify any pregnanediol, but in a similar study of pregnant goat urine[7] they found a pregnanediol concentration of 2 mgm. per litre.

As part of an investigation on progesterone metabolism in the ewe, 20 l. of pooled urine from ten pregnant ewes in the fourth month of pregnancy were hydrolysed, extracted by the usual methods, and chromatographed on alumina.

The fraction corresponding to 5β-pregnane 3α : 20α-diol, yielded, after recrystallization from ethanol–water, 35 mgm. of white crystals which melted at 234–236° C. and gave no depression when a mixed melting point was determined with authentic 5β-pregnane 3α : 20α-diol. The infra-red spectra of this material matched that of authentic pregnanediol.

The work was repeated on 10 l. of pregnancy urine collected from other ewes a year later and a similar result was obtained. 10 l. of urine from anœstrous ewes was investigated by similar methods and no trace of pregnanediol was found.

Ribosyl Transfer between Ribose Nucleotides in the Rat

IN the course of studies on alterations in the rate of catabolism of nucleic acids induced by radiation after total body exposure of rats, evidence has been obtained of the existence of an exchange between the ribosyl residues of purines and pyrimidines and urinary imidazole acetic riboside. The latter riboside has served as a measure of the isotope concentration in the ribose pool of the rat. Hiatt *et al.*[1] have reported recently an application of this 'metabolic trap' to the study of mechanisms by which glucose is metabolized *in vivo*, particularly with respect to the contribution of the glucose-6-phosphate oxidative shunt to the metabolism of glucose. The use of imidazole acetic riboside as a device for trapping ribosyl residues has been made possible by the findings of Tabor and his collaborators[2,3], who have demonstrated that imidazole acetic riboside is one of the major urinary excretion products of imidazole acetic acid.

In a typical experiment, a rat weighing 194 gm. was injected intraperitoneally with 2 μc. of cytidylic acid-^{14}C (uniformly labelled) equivalent to $8 \cdot 5 \times 10^5$ c.p.m. and 8 mgm. of imidazole acetic acid. Urine was collected for 20 hr. thereafter; the rat was killed at the end of the 20-hr. period.

The ribonucleic acid fraction of the liver was isolated as described by Paine *et al.*[4]. The (free) nucleotide fraction soluble in acid was adsorbed on activated charcoal ('Norite' *A*) from the supernatant resulting from treatment with perchloric acid and was then eluted according to the procedure of Cabib *et al.*[5]. The nucleotide polyphosphates thus obtained were converted to their corresponding monophosphates which, in turn, were separated by paper chromatography[6]. The ribonucleic acid fraction was hydrolysed by Schmidt and Thannhauser's method[7] and the resulting nucleotides separated and isolated by Hurlbert and Potter's procedure[8].

The isolation of imidazole acetic acid from urine was accomplished as follows: (*a*) Removal of substances insoluble in 66 per cent aqueous methanol (v/v); (*b*) placing the methanol-soluble fraction on a column of 'Amberlite 120'(H+), removal of glucose and pentoses by washing the column with water, and elution of the riboside with 2 *M* ammonium hydroxide; (*c*) final purification of the effluent fraction containing riboside by means of paper chromatography in two different solvent systems[2]. Imidazole acetic riboside was eluted from the paper strips with methanol. The methanol was distilled off and the riboside concentration was determined quantitatively in an aqueous solution of the residue in terms of periodate consumption[9]. The aqueous washings of the 'Amberlite 120' column were passed through a column of 'Amberlite *IR* 400' (acetate form, 16–50 mesh). Glucose and pentoses were not retained by this column and were isolated from the effluent solution by paper chromatography[10]. After treatment of the paper strips with aniline phthalate, appropriate areas of the chromatograms were eluted with methanolic acetic acid (5 per cent). These eluates were then used for the determination of chemical and isotopic concentrations of the respective carbohydrates.

Details concerning the isolation procedure and chemical determination of the urinary carbohydrates will be published elsewhere. All determinations of radioactivity were carried out with a gas-flow counter using 'infinitely thin' layers of the compounds on polyethylene planchets, 2·5 cm. in diameter. The results are presented in Table 1.

Table 1. INCORPORATION OF CARBON-14 ACTIVITY IN VARIOUS COMPOUNDS RELATED TO THE RIBOSE POOL AFTER INJECTION OF CYTIDYLIC ACID-^{14}C (UNIFORMLY LABELLED)

Source	Compound isolated	Micromolar carbon-14 activity (c.p.m./μM)
Liver	Ribonucleic acid nucleotides	
	Cytidylic acid*	185
	Uridylic acid	120
	Adenylic acid	44
	Guanylic acid	40
	Acid-soluble nucleotides (free)	
	Adenylic acid	30
	Uridylic acid	300
	Glycogen (as glucose)	1
Urine	Imidazole acetic riboside	320
	Ribulose	305
	Xylulose	360
	Glucose	47

* The micromolar carbon-14 activity ratio of cytosine/ribosyl moiety was 0·31.

The following conclusions have been drawn from the results obtained: (1) The findings suggest the occurrence of transfer of ribosyl residues of cytidylic acid to imidazole acetic riboside as well as to free and ribonucleic acid-bound uridylic and adenylic acid in the liver. (2) The micromolar carbon-14 activity of the free urinary pentoses equals approximately that of the ribosyl moiety of imidazole acetic riboside, suggesting that incorporation of carbon-14 into the latter ribosyl moiety has occurred largely by way of phosphorolytic cleavage followed by pentose interconversions. (3) The results indicate that the contribution of cytidylic acid ^{14}C (uniformly labelled) to the labelling of purine nucleotides in the liver, either free or bound to ribonucleic acid, is of minor importance. (4) The low isotope concentration of urinary glucose suggests that the carbon atoms of the ribosyl moiety are probably not in equilibrium with the carbon atoms of glucose.

We are indebted to Dr. H. Tabor for making available some unpublished information regarding imidazole acetic acid and imidazole acetic riboside.

This work was supported in part by a grant from the U.S. Atomic Energy Commission.

Selenium and Liver Necrosis in the Hyperthyroid Rat

It is well known that dietary deficiencies can be seriously aggravated by the induction of a hyperthyroid state. Recently it has been shown[1-3] that selenium significantly prolongs the survival-time of rats and prevents the onset of the liver necrosis which follows the ingestion of a diet containing yeast as the only source of protein. This protective effect of selenium resembles that shown by a number of apparently unrelated substances such as methionine, cystin, vitamin E, methylene blue and methylthiouracil, the mode of action of which is not understood. Unpublished observations, made in the course of a systematic investigation into the effects of various hormonal and nutritional stimuli on the course of liver necrosis, had suggested that it might be possible to distinguish between a true protective effect and a 'non-specific', indirect effect of the substances tested by the induction of a hyperthyroid state. Methylthiouracil, for example, which protects the euthyroid weanling rat against the onset of liver necrosis, was ineffective in litter-mates made hyperthyroid by the simultaneous addition of thyroid powder to the diet. A somewhat similar effect was seen if methylene blue was given, in contrast to the persistence of the protective effect obtained if vitamin E was used. In the light of these considerations it was thought of interest to see how the induction of a hyperthyroid state would affect the protective effect of selenium in dietary liver necrosis.

Male litter-mate rats of a strain bred in the Department of Anatomy, Birmingham, were weaned on the twenty-first day of life, the first day of the experiment, and were fed the 'necrogenic yeast diet' of Lindan and Himsworth[4] to which thyroid powder and sodium selenite had been added. The dose of selenium was kept constant at a level of 0·00002 per cent, but the level of thyroid powder was increased from 0·2 per cent (Exp. 1) to 0·3 per cent (Exp. 2) and 0·5 per cent (Exp. 3). All animals were kept in individual cages with raised screen floors, and were allowed to die spontaneously. The survival times and the incidence of liver necrosis are presented in Table 1. It can be seen that the induction of hyperthyroidism significantly accelerated the onset of liver necrosis, but that despite the presence of even a severe hyperthyroid state (Exp. 3), the small amount of selenium given prevented the development of dietary liver necrosis. Although the difference in the survival times of the rats fed the highest amount of thyroid powder with and without selenium was not significant, the absence of liver necrosis was striking. This protective action of selenium, in the presence of varying degrees of hyperthyroidism, is suggestive of a direct effect of selenium, and is best interpreted as the alleviation of a true deficiency. In view of the observations of Bunyan, Edwin and Green[2] on the protective effects of trace elements other than selenium, it would be of interest to see what effect the induction of a hyperthyroid state would have on the action of these trace elements.

Table 1. The Effect of Varying Levels of Thyroid Hormone with and without Selenium on the Survival Time (in days) of Litter-mate Rats fed the 'Neorogenic Yeast Diet'.
(Incidence of liver necrosis in parentheses)

Level of thyroid hormone	No. of animals	Necrogenic diet	Necrogenic diet plus thyroid hormone	Necrogenic diet plus thyroid hormone plus sodium selenite (0·00002 per cent)
Exp. 1: 0·2 per cent	7	40·4 ± 5·42 (7/7)	25·0 ± 1·02 (7/7)	59·4 ± 9·48 (1/7)
Exp. 2: 0·3 per cent	7	29·3 ± 1·25 (7/7)	19·6 ± 0·68 (7/7)	33·9 ± 3·54 (0/7)
Exp. 3: 0·5 per cent	8	23·3 ± 2·33 (8/8)	16·7 ± 0·50 (8/8)	20·5 ± 2·19 (0/8)

Another point of interest is the effect of supplements of selenium on the course of the hyperthyroid state itself. Although the addition of thyroid powder to the diet significantly ($P < 0.001$) hastened the onset of liver necrosis in all the animals, increasing the dose of thyroid powder from 0·2 to 0·3 or 0·5 per cent had no significant effect on the survival times if each group was compared with the untreated litter-mate controls. (The spontaneous decrease in the survival times of the untreated controls of Exps. 1–3, seen in Table 1, is purely accidental.) This is in contrast to the obvious decrease in survival times found with increasing doses of thyroid hormone, if selenium is given in the diet as well. By comparison with the litter-mates given thyroid only, the regression was significant at the 5 per cent level using a 'two-sided' test. This observation again suggests that selenium acts by alleviating a dietary deficiency, and underlines the caution which is indicated if the effects of the pure, uncomplicated hyperthyroid state are to be clearly assessed.

I should like to thank Dr. D. Darlington for the statistical analysis of the data.

Utilization of the Carboxyl Group of Glycine for the Synthesis of the Amino-Acids of Silk by *Bombyx mori*

WHEN fasting and ready to spin their cocoons, five silkworms were each injected with 112 μgm. (2·1 μc.) of glycine-1-^{14}C.

Fibroin was isolated from the cocoons by the method described by Dunn *et al.*[1]. The four amino-acids—tyrosine, glycine, alanine and serine—were then isolated from the hydrolysed fibroin, using a modification of Stein and Moore's procedure[2]: the hydrolysed fibroin was freed of excess hydrochloric acid by repeated evaporation and then by percolating through a bed of 'Amberlite' *IR* 120 (H^+). The amino-acids adsorbed on the resin were eluted with 3 *N* ammonia, which was then evaporated *in vacuo*. At this stage, the tyrosine was removed by filtration and purified by crystallization and finally by chromatography on a starch column, with butanol/water as solvent[3]. Tyrosine was completely radio-inactive. Glycine was precipitated as glycine nitronaphthalene sulphonate, alanine as azobenzene-*p*-sulphonate and serine as *p*-hydroxyazobenzene-*p*-sulphonate. The amino-acids were obtained by passing the sulphonates through an 'Amberlite' *IR* 120 (H^+) column and then eluting with 3 *N* ammonia. They were crystallized several times in water–ethanol–diethylether.

The specific activities of the sulphonates and of the derived amino-acids remained constant throughout the crystallizations. The chemical purity of each amino-acid was checked by Kjeldahl nitrogen analysis and by paper chromatography in butanol/hydrochloric acid and in phenol/water. They were then oxidized and converted to barium carbonate. The radioactivity measurements were performed with a thin mica-window Geiger counter on barium carbonate deposits. Each amino-acid was decarboxylated with ninhydrin[4]. The carbon dioxide evolved was trapped in sodium hydroxide solution and converted to barium carbonate. The radioactivities of the isolated amino-acids and of their carboxyl groups, corrected for background and self-absorption[3], are summarized in Table 1.

Table 1

	Specific activities		Total activity per cocoon (counts/min.)
	Amino-acid (counts/min./mmole)	Carboxyl group (counts/min./m.equiv.)	
Injected glycine	$2 \cdot 7 \times 10^8$	$2 \cdot 7 \times 10^8$	
Isolated glycine	196,000	196,000	81,500
Isolated serine	65,700	63,600	7,500
Isolated alanine	18,200	18,600	5,400
Isolated tyrosine	0	0	0
			94,400

Total activity injected per worm, 400,000 counts/min.

From these results, one can conclude that: (1) One quarter of the total activity injected appeared in silk fibroin. (2) The injected glycine was found diluted about one thousand-fold in the silk, which was most probably not uniformly labelled. (3) Direct conversion of glycine to serine keeping the label in the C-1 position occurs in the silkworm. It is probably the result of the addition of a one-carbon unit as shown in mammals, birds and micro-organisms. (4) There is also a conversion of glycine to alanine which might proceed through serine and pyruvic acid. Whatever the steps of this transformation are, the reactions involved must introduce the C-1 of glycine exclusively into the carboxyl group of alanine. (5) Tyrosine has not incorporated any radioactivity from glycine-^{14}C, whereas in a previous communication we have shown a direct conversion of phenylalanine to tyrosine[6]. This seems to indicate that the phenylalanine-tyrosine pair is essential to the silkworm.

Utilization of Formate for the Biosynthesis of Glycine Carbon-1 and -2 in *Bombyx mori*

JUST prior to spinning their cocoons, each of twenty silkworms was injected with 1·7 mgm. (25 μc.) of formate labelled with carbon-14. The fibroin, isolated by the method of Dunn *et* al.[1], was hydrolysed and the glycine isolated as nitronaphthalene sulphonate. This salt was recrystallized several times, then dissociated on a 'Dowex' 50 column; free glycine was eluted with 3 *N* ammonia and crystallized in water/ethanol/diethylether. Its chemical purity was checked by paper chromatography in two different solvents (phenol/*iso*propyl alcohol/water and butanol/acetic acid/water). The specific radioactivities of the nitronaphthalene sulphonate and of the free glycine remained constant throughout the recrystallizations.

The isolated glycine was decarboxylated[2]; C-1 was isolated as barium carbonate and C-2 as formaldimedone. The specific activities of the isolated glycine and of its two carbons are shown in Table 1; all determinations were performed with a thin mica-window Geiger counter on barium carbonate deposits (glycine and formaldimedone were oxidized and converted to barium carbonate before the assays) and the results corrected for background and self-absorption.

The degradation procedure was checked on synthetic glycine-1-^{14}C and glycine-2-^{14}C (Table 1).

It can be concluded that formate carbon is utilized for the synthesis of glycine C-1 and C-2 in *Bombyx mori.* 1·5 per cent of the injected radioactivity appeared in the fibroin glycine, while 2 per cent was found in fibroin serine which had a specific activity about six times greater than glycine.

Several biochemical pathways, known in other organisms, can be suggested to explain these results. Further work, namely the analysis of the distribution

Table 1. SPECIFIC ACTIVITIES
(counts/min./mmole or m.equiv.)

	Isolated	1-^{14}C	2-^{14}C
Glycine	68,400	33,600	280,000
C-1	20,300	33,800	158
C-2	43,500	42	277,000

of carbon-14 in serine and alanine isolated from the silk fibroin, can help us to decide which of these routes is the most important in *Bombyx mori*. We already know that the administration of glycine-1-^{14}C is not followed by a redistribution of the labelled carbon between the two carbons (see preceding communication).

Cellulolytic Activity of Phytopathogenic Bacteria

As the great majority of phytopathogenic bacteria are extracellular parasites occupying chiefly the vessels and the intercellular spaces, and causing vascular diseases, soft-rots, spot diseases, etc., the ability to decompose the surrounding walls composed of pectin and cellulose is supposed to be an important factor controlling the destruction and/or enlargement of the tissues attacked. Although Husain and Kelman[1] reported the presence of cellulase in diseased tomato tissues infected by *Pseudomonas solanacearum*, our knowledge of the cellulolytic enzymes is poor in comparison with that in the field of pectolytic enzyme studies of plant pathogens.

We have sought evidence *in vitro* as to whether cellulolytic enzymes are produced by other phytopathogenic bacteria. Bacterial species or isolates used were from our collections in Japan. For the recognition of cellulolytic enzymes carboxymethylcellulose gel medium was used as stab cultures and observed periodically for three weeks at an incubation temperature of 30° C. When the enzymes were produced, stratiform liquefaction of the gel followed the growth of bacterial species inoculated. The carboxylmethylcellulose gel medium was prepared as follows: 2 per cent of carboxymethylcellulose (Koso Chem. Co., Ltd., Tokyo) was dissolved in hot basal medium (70° C.) such as bouillon, potato decoction, synthetic solution *A* (ammonium dihydrogen phosphate, 1 gm.; potassium chloride, 0·2 gm.; magnesium sulphate, 0·2 gm.; distilled water, 1 l.); synthetic solution *B* (ammonium nitrate, 1 gm.; potassium hydrogen phosphate, 1 gm.; magnesium sulphate, 0·2 gm.; distilled water, 1 l.); or synthetic solution *C* (Uschinsky's solution without glycerol), then heated almost to boiling point and stirred sufficiently to form a homologous gel. The mixtures were placed in tubes and autoclaved at 15 lb./in.^{2} for 10 min. Tests were made with 13 species of *Pseudomonas*, 7 species of *Xanthomonas*, 2 species of *Erwinia*, 1 species of *Agrobacterium* and *Corynebacterium*, including various isolates of each species.

Prompt liquefaction of the gel was observed in bouillon and potato decoction cultures after 3–5 days, while in synthetic media the gel was liquefied very slowly and some isolates showed only partial liquefaction even after three weeks. The liquefying species or isolates grew well throughout the dissolved layers of gel. Growth of the non-liquefying ones was moderate on the gel surface in bouillon and potato decoction, but feeble or absent in synthetic media.

The results, obtained from potato-decoction gel cultures, showed that cellulolytic enzymes are produced from *Ps. panici* (syn. *Ps. setariae*), *Ps. solanacearum*, *Xanthomonas campestris*, *X. citri*, *X. nigromaculans*, *X. oryzae*, *X. pisi* (a new species, not reported), *X. pruni*, *X. vesicatoria*, *Erwinia carotovora* (including *E. aroideae* as a synonym), *E. milletiae*, *Corynebacterium sepedonicum*, but not from *Ps. aeruginosa*, *Ps. andropogoni*, *Ps. cichorii*, *Ps. eriobotryae*, *Ps. iridicola*, *Ps. maculicola*, *Ps. marginalis*, *Ps. marginata*, *Ps. phaseolicola*, *Ps. syringae*, *Ps. tabaci*, *Ps. theae* and *Agrobacterium tumefaciens*.

In the case of *X. oryzae*, *E. carotovora* and *Ps. solanacearum*, the rapidity of liquefaction varied with the kinds of isolates used.

The pathological significance and biochemical characteristics of the cellulolytic enzyme produced by these bacteria will be discussed elsewhere.

The Kidney and Erythropoiesis

IT has been pointed out[1,2] that, in the dog, bilateral nephrectomy abolishes erythropoiesis, and it was suggested that the kidney produces a factor stimulating red blood cell formation. The experimental result did not definitely exclude retention of some toxic substance that inhibits the erythropoiesis, since the nephrectomized animals were still uræmic (blood urea level at about 300 mgm. per cent) despite peritoneal dialysis.

In further experiments an attempt was made to dissociate a toxic effect from the lack of some erythropoietic factor of renal origin. Thus, erythropoiesis was studied in a group of eight dogs submitted to bilateral ureter ligation. This group was compared with one group of seven intact and one group of eight bilaterally nephrectomized animals.

Bone-marrow samples were examined every other day before and after surgery. 72 hr. after surgery, 5 μc. of iron-59, previously incubated in 20 ml. plasma, were given intravenously. The uptake of iron-59 into erythrocytes was measured in eight dogs during the three following days.

Five dogs lived long enough to allow studies of the maximal incorporation of iron-59. The dogs with ligated ureters as well as the nephrectomized ones refused food, and were given two or three daily peritoneal dialyses, thus reaching similar levels of toxic retention and malnutrition.

Despite these conditions, the following experiments show that erythropoiesis is almost normal in animals with ureteral ligation, showing that the absence of a kidney-factor is responsible for the impaired erythropoiesis in nephrectomized dogs.

The disappearance curves of iron-59 from the plasma are similar in normal dogs (39–153 min.) and in those with ligated ureters (64–171 min.). The average time at which half the radioactivity initially present has disappeared ($T/2$) is 299 min. in the nephrectomized, 89 in the normal animals and 96 in those with ligated ureters.

The rate of turnover of plasma iron is higher in animals with ligated ureters (0·25–0·85 mgm./kgm./day; mean, 0·48) than in nephrectomized ones

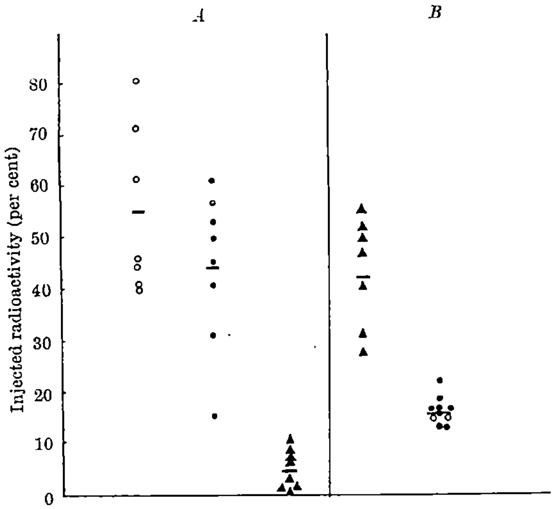

Fig. 1. (*A*) Uptake of iron-59 into erythrocytes. ○, Normal dogs 72 hr. after injection of iron-59; ●, dogs with ligated ureters 72 hr. after injection of iron-59; ▲, maximal uptake in nephrectomized dogs; —, mean. (*B*) Uptake of iron-59 into liver. ○, Normal dogs; ●, dogs with ligated ureters; ▲, nephrectomized dogs; —, mean

(0·09–0·49 mgm./kgm. day; mean, 0·24); the differences observed are statistically significant ($P < 0 \cdot 01$). It is slightly lower than in normal animals (0·25–0·92 mgm./kgm./day; mean 0·64) but these differences are not significant ($0 \cdot 1 < P < 0 \cdot 2$).

The incorporation of iron-59 into red cells three days after injection of the isotope is almost the same in dogs with ligated ureters (15·6–60·9 per cent; mean, 44·1) as in normal animals (40–80·8 per cent; mean, 55·3), while it is less than 12 per cent in the nephrectomized dogs, 8 and even 10 days after the isotope administration. Maximal incorporation averages about 70 per cent in the normal and 61 per cent in the five dogs with ligated ureters (Figs. 1 and 2).

Our observations included an estimation of erythropoiesis by post-mortem measurements of radioactivity in the liver (Fig. 2). This radioactivity varies from 27 to 55 per cent (mean, 43·3 per cent) of the injected tracer dose in the group of seven bilaterally nephrectomized dogs and from 13 to 22 per cent (mean, 16·1 per cent) in the control group of dogs with ligated ureters and in two normal dogs. This suggests that in the controls iron-59 is chiefly deposited in erythropoietic organs. We also regard as noteworthy the persistence of erythroblasts in the bone-marrow of dogs with ligated ureters, since these elements disappear three days after bilateral nephrectomy.

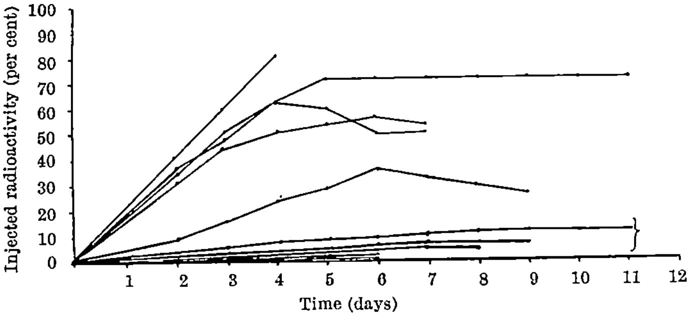

Fig. 2. Uptake of iron-59 into erythrocytes. The curves in the bracket are for nephrectomized dogs, the others for dogs with ligated ureters

These observations lead to the conclusion that the kidney produces an erythropoietic-stimulating factor, or transforms some precursor into an active agent. Besides this, it was shown that retention of toxic products does not impair erythropoiesis.

Our results agree with those of Jacobson[3] working on rats, but diverge from the observations of Mirand and Prentice, who noted an erythropoietic response in anoxic nephrectomized rats[4].

Effect of Drugs on Conditioning and Habituation to Arousal Stimuli in Animals

Previous studies[1,2] using the feline *encéphale isolé* of Bremer have shown differential effects of certain drugs on the thresholds for electrocortical activation and behavioural arousal from sleep produced by auditory stimulation. In order to confirm and extend these results further experiments were carried out in conscious, chronic cat preparations carrying permanently implanted cortical recording electrodes[3]. For recording purposes these animals were placed in a constant-environment chamber fitted with a one-way glass window. Auditory stimuli were presented from a loudspeaker fitted in a side wall of the chamber, and the threshold for arousal was taken as the intensity of stimulation necessary to bring about abrupt desynchronization of the electrocorticogram and behavioural arousal.

It is clear that in any comparative study of the changes produced by drugs in the behavioural and electrocortical arousal reaction evoked by repeated sensory stimulation, we must take into consideration the normal processes which occur simultaneously. For example, in the present study the thresholds for arousal produced by a given auditory stimulus were not the same in every animal, and in any one animal they tended to fluctuate from day to day. In addition, the thresholds for a particular stimulus, although remaining constant when determined two or three times over a 4-hr. period, tended to increase when the stimulus was continually repeated over a similar period of time.

Habituation of the arousal reaction therefore developed very rapidly in these preparations where minimal intensities of auditory stimulation were employed, and it was found that the thresholds for auditory-induced arousal responses were only constant from approximately the first to the fifth presentation. This does not present a very stable base-line on which to test the effects of incremental doses of drugs. Sharpless and Jasper[4], however, have shown that habituation to a stimulus may be overcome by positive conditioning, and

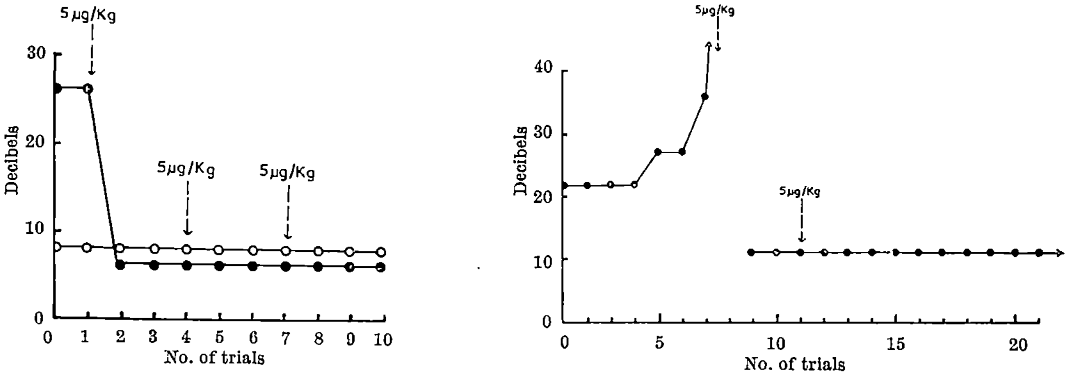

Fig. 1A

Fig. 1B

Fig. 1. *A*, The effect of lysergic acid diethylamide on conditioned and unconditioned auditory-induced arousal responses. *B*, The effect of lysergic acid diethylamide on habituation of the arousal reaction. ●, Threshold for unconditioned arousal; ○, threshold for conditioned arousal

therefore all preparations used in this study were conditioned to arouse upon the presentation of a specific tone. The conditioned response, consisting of both electrocortical desynchronization and behavioural arousal from sleep, was obtained by pairing an electric shock with the particular tone chosen. In doing this it was found that the arousal thresholds remained stable from day to day and the stimulus could be repeatedly presented at short intervals for something like 30–40 trials before extinction took place. It is interesting to note that during the conditioning trials the thresholds for electroencephalographic and behavioural arousal produced by the conditioned stimulus progressively decreased in every animal to a level approaching the threshold of hearing.

In all the experiments carried out with chronic unrestrained preparations the drugs were injected by the intraperitoneal route. Chlorpromazine in doses of 5–10 mgm./kgm. produced a rise in the thresholds for conditioned and unconditioned auditory-induced arousal responses. Following a total dose of 15–20 mgm./kgm., the conditioned as well as the unconditioned arousal response was blocked completely even when the intensity of the stimulus was considerably increased above control levels. At this point visual and tactile stimuli which normally evoked arousal responses failed to do so.

Reserpine also produced an increase in the arousal thresholds. Since this drug appears to have a delayed action incremental doses were not given. Instead, a single dose of 200 or 250 µgm./kgm. was injected and the thresholds then checked every half-hour over a 5-hr. period. The effects of reserpine were very slow to appear, and no significant effect was observed until 1–1½ hr. after the injection, when the thresholds for conditioned and unconditioned auditory-induced arousal showed a slight rise. After 2–3 hr., however, a dissociation of the threshold/time response curves became apparent. The thresholds for the unconditioned response rose progressively until 3½ hr. after the injection arousal produced by the neutral stimulus was blocked completely. On the other hand, the threshold for the conditioned response remained constant or rose a further step but in no case was the conditioned response blocked by reserpine. Moreover, the animal still responded to novel stimuli, which suggests that the blocking of the unconditioned response might be due to habituation.

The effect of lysergic acid diethylamide was tested on conditioned and unconditioned arousal responses. In addition, the animal was also habituated to an auditory stimulus by continued presentation over a short period of time. After an initial dose of 5 µgm./kgm. of lysergic acid diethylamide conditioned arousal responses remained unaffected but the threshold for the unconditioned response fell sharply (Fig. 1*A*). Similarly, the stimulus to which the animal had become habituated now evoked a marked response. The intensity of the stimulus needed to produce this effect was also much lower than the original level (Fig. 1*B*). Following a total dose of 10–15 µgm./kgm. of lysergic acid diethylamide the animal became more responsive to sensory stimulation and remained alert for long periods. The thresholds for arousal, however, did not show any further change.

The arousal value of a sensory stimulus depends upon the significance which is attached to it by the animal. Positive conditioning increases the significance, whereas during habituation there is a loss of significance. In these experiments chlorpromazine appeared to simulate the effects of habituation for a wide range of sensory stimuli, the animal becoming indifferent to stimuli which previously had evoked electrocortical activation and behavioural arousal. In contrast, lysergic acid diethylamide appeared to increase the significance of most sensory stimuli to a level similar to that achieved by positive conditioning for any given stimulus. The fact that both lysergic acid diethylamide and chlorpromazine produced no marked effect on the thresholds for arousal evoked by direct stimulation of the brain stem reticular formation[2], and yet have an effect on auditory-induced arousal responses, emphasizes the importance of the neural mechanisms regulating the inflow of sensory information in relation to the action of these drugs.

The blocking of the unconditioned arousal responses following reserpine can, as already stated, be explained on the basis of habituation, since novel stimuli were still capable of producing arousal. Thus in contrast to chlorpromazine, it would appear that the sedation produced by reserpine does not seem to be entirely dependent upon the action related to the inflow of impulses into the brain stem from the classical sensory pathways. The site of action of reserpine cannot be defined at this stage, but it is interesting to note that reserpine did not block the conditioned arousal responses, whereas numerous workers have reported that this drug severely depresses conditioned avoidance behaviour[6]. The use of conditioned arousal responses eliminates a task involving muscular co-ordination, and it may well be that responses of this sort may help to distinguish more clearly the selective effects of some drugs from a more diffuse and non-specific action of others.

Lenticular Effect in Mice of Some Morphine-like Drugs

Drug-induced opacities of the lens of the eye have been recorded by Busche[1] using nitrophenol compounds in chicken. He was unable to produce this in any other small animals except in one particular strain of mice. While investigating the acute toxic effects of a series of reversed esters of pethidine, we observed that a number of these also produced an opacity. This was completely reversible and has been obtained by using other analgesic drugs in several strains of mice.

Fig. 1 shows the typical reaction seen in the eyes of mice after subcutaneous injection of 2 mgm. of (DL)-methadone hydrochloride. All doses mentioned are expressed as mgm./100 gm. of body-weight, and the mice used (both sexes) weighed 18–22 gm. The cloudiness begins to appear at 15 min., reaching a maximum in 50 min., when it slowly disappears. 3 hr. later, the eye is clear again. Smaller doses produce less effect. The opacity develops more slowly with morphine, reaching a maximum in 75–90 min. The effect can be produced in rats but less readily. This species is more sensitive to other toxic actions of these drugs so that the blood concentration to produce an opacity would usually be lethal.

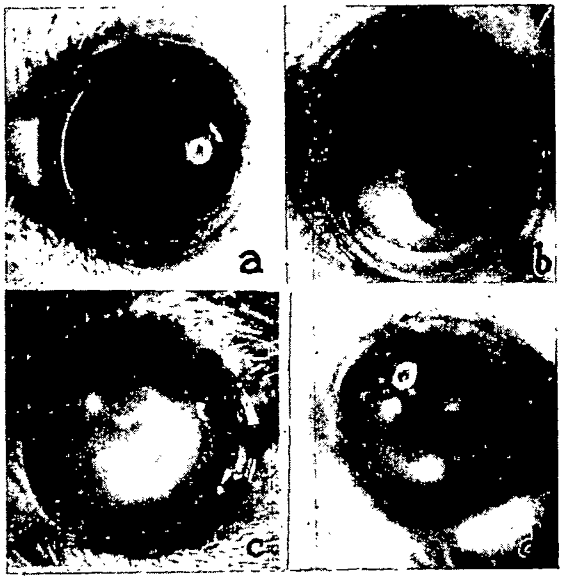

Fig. 1. Various degrees of eye opacity developing in the lens after subcutaneous injection (2 mgm./100 gm.) of (DL)-methadone hydrochloride: (*a*) normal eye; (*b*) 30 min.; (*c*) 50 min.; (*d*) 75 min.

The cloudiness developed in the lens while the cornea remained clear when the eye was viewed through a slit-lamp microscope. Removal of the lens confirmed the site of the opacity. Further investigation has shown that in the intact animal clouding takes place on the anterior surface of the capsule while the lens itself remains transparent. In isolated normal lenses exposed to the same drugs, similar changes occur, but the whole capsule is involved.

A range of drugs has been tested to determine whether the production of this opacity is confined to a certain class of compound. This was found to be the case with narcotic drugs, and particularly with the potent analgesic members of this group. The exceptions were cocaine and papaverine, which had only one-tenth to one-twentieth of the activity of methadone. This effect was produced in at least 20 per cent of the mice by subcutaneous injection, in doses less than 5 mgm., of pethidine hydrochloride and three of its reversed esters (to be published in detail elsewhere); of morphine sulphate and some of its structural analogues, and of (DL)-methadone hydrochloride. Of those tested, the more active the drug was as an analgesic the more readily it produced an opacity.

No effect could be obtained by sublethal doses of the following drugs:

Codeine phosphate
Apomorphine hydrochloride
Mepyramine maleate
Diphenhydramine hydrochloride
Histamine acid phosphate
Atropine sulphate
Physostigmine salicylate
Quinidine sulphate
Amiphenazole hydrochloride
Pentobarbitone sodium
Cyclobarbitone sodium
Phenobarbitone sodium
Acetyl-salicylic acid
N-acetyl-*para*-amino phenol
Phenacetin
Lignocaine hydrochloride
Amethocaine hydrochloride
Procaine hydrochloride

This additional activity of these analgesic drugs has been studied in more detail. In Table 1 a comparison is made of the dose which will produce analgesia in 50 per cent of the mice (*ED*50) as determined by the 'tail clip' method[2], the dose which will kill 50 per cent of the mice (*LD*50) and the dose which will cause cloudiness in 20 per cent of the mice (minimum opacity dose). In each case the dose required to produce the opacity is greater than the corresponding *ED*50, but less than the *LD*50. By changing from the subcutaneous to the intravenous route, clouding of the lens, analgesia and toxicity are increased by all three drugs. When any of these are given intraperitoneally they become less active both as analgesics and in their effect on the eye, yet they are more toxic. Thus it appears that the production of opacity follows the degree of analgesia more closely than the lethal action of these drugs.

The lenticular opacity produced by analgesic drugs can be prevented by the simultaneous injection of

Table 1. Minimum Doses to produce Opacity and Analgesia compared with those for Lethal Effects by Different Routes

Analgesic drugs	Route	*ED*50 (mgm./100 gm.)	Minimum opacity dose (mgm./100 gm.)	*LD*50 (mgm./100 gm.)
Morphine	s.c.	0·5	4·0	50
	i.p.	0·8	6·0	31
	i.v.	0·4	2·5	15
Pethidine	s.c.	1·4	5·0	17
	i.p.	3·1	7·5	12
	i.v.	1·2	2·0	4
Methadone	s.c.	0·3	1·0	4·0
	i.p.	0·4	1·5	2·8
	i.v.	0·3	0·75	1·5

small doses of nalorphine. Furthermore, if the effect has already developed, this antagonist will cause it to disappear in less than one-fifth of the normal time. Nalorphine itself can produce this opacity also but only with doses greater than 50 mgm. As expected, the cloudiness produced by cocaine could not be antagonized in this way.

The modification of this effect by other agents is being investigated. An examination of the actions of these drugs on enucleated lenses is also being carried out because in contrast to the *in vivo* experiments such opacities can be produced by compounds differing widely in pharmacological properties. A detailed report of this work will be published elsewhere.

Dependence on Age of the Diameter of the Pupil in the Dark

The dependence of the diameter of the pupil of the human eye in the dark on the age of the subject, derived from a large amount of statistical material, is important not only for ophthalmology and neurology but also for physiological and practical optics.

Very little work has been done on this subject, however, and in ophthalmological and optical literature therefore only the values of old measurements after Trendelenburg[1-5] are given (Fig. 1).

In 1950, Birren *et al.*[6] published values for the vertical diameters of the left eyes of 216 subjects in the dark after 90 sec. adaptation, obtained by flash photography with visible light. These differed substantially from Trendelenburg's values (Fig. 1).

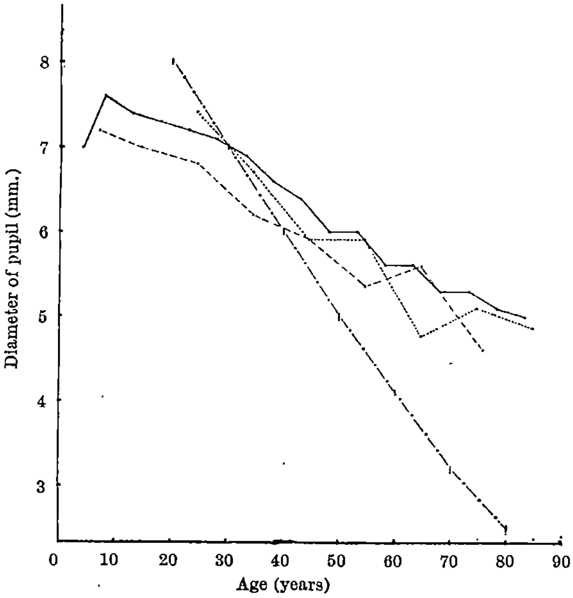

Fig. 1. Mean values of the apparent diameter of pupil in the dark as a function of age according to: Trendelenburg, —·—·—; Birren, ...; Seitz, – – – –; Kadlecová, Peleška and Vaško, ———

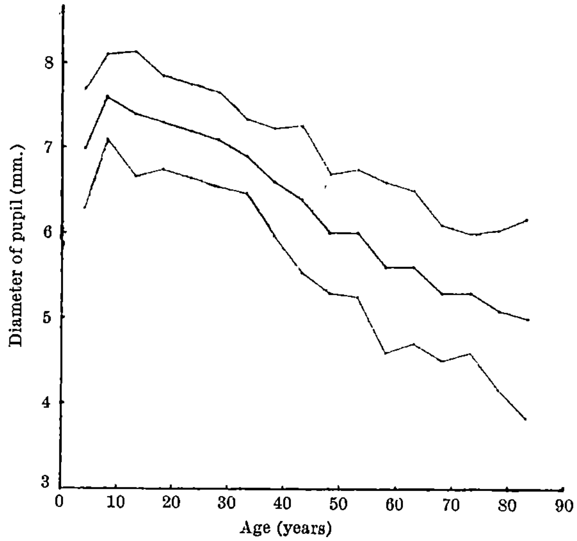

Fig. 2. Mean values of diameter of pupil in the dark with corresponding root-mean-square errors of one measurement as a function of age according to Kadlecová, Peleška and Vaško

Since 1946 we have been measuring the diameter of the pupil in the dark by infra-red radiation—thus eliminating all effects of visible light—with an image converter[7]. The mean values obtained by us for 906 horizontal diameters of both pupils of 453 normal subjects in the dark after 15 min. adaptation are also plotted in Fig. 1. Each subject was clinically examined and cases with diseased iris and nervous system were eliminated.

Later, Seitz published[8] measurements on 208 subjects, made by flash photography in visible light after adaptation for 1 hr. in the dark. These have also been included in Fig. 1, after correcting the mean value of the diameter of the pupil for the age group 40–49 years from 5·1 mm. to 5·9 mm.

In Fig. 2 are plotted the mean values of our measurements giving the corresponding root-mean-square errors δ, calculated from the relation:

$$\delta = \pm \sqrt{\frac{\Sigma\Delta^2}{n-1}}$$

A comparison of these results shows that for young subjects up to about thirty years of age our measurements give lower values than those of Trendelenburg, while from thirty upwards the values are higher and the differences increase with increasing age. The measurements of Birren *et al.* agree approximately with our measurements but are somewhat lower. Seitz's measurements are mostly lower than ours but his curve is practically parallel to our curve.

The accuracy of our method permitting visual observation of the infra-red image of the eye is certainly much greater than methods using flash photography in the dark, since the uncertainty in focusing the image of the pupil after a longer period of adaptation in the dark is removed. Other authors themselves point out the difficulty in maintaining focus[8]. Moreover, as our observations showed, the pupil in the dark is not absolutely at rest and can be seen to perform occasional very fine contractions. Our visual method enables such contractions to be eliminated and the real maximum diameter of the pupil to be measured. Our measurements showed that the diameter does not depend on sex or on the colour of the iris. The diameters of the pupils of both eyes were found to be the same. We found, however (Fig. 2), a visible increase in the mean error (dispersion of values) with age.

Influence of Hydrocortisone on the Action of Sodium on Isolated Rabbit Auricles

SZENT-GYÖRGYI[1] has demonstrated the importance of the 'intracellular ionic atmosphere' on the contraction of the cardiac muscle, and has suggested that adreno-cortical steroids may influence cellular activity by alterations in membrane permeability. It has also been shown by Selye and Renaud[2] that the action of electrolytes on the heart is influenced by what is termed the 'conditioning' effect of hormones. Further, Holland[3] has presented evidence to show that antiarrhythmic drugs act on the atria by depressing the transmembrane flux of sodium and potassium ions. In this connexion, it would be of interest to examine the effect of the steroid hormones on the action of the ions on the heart. It is well known that when the heart is kept in a medium containing sodium as the only ion it stops beating after some time. Later, when the medium is changed to Ringer solution, the beat recommences, presumably due to sodium extrusion. If a steroid hormone altered the permeability of the cell membrane, it would modify the action of sodium by interfering with sodium traffic across the membrane.

In order to examine this possibility, isolated rabbit atria were kept in oxygenated Ringer solution in a thermostatic organ bath at 37° C. and the contractions recorded on a kymograph. After obtaining normal contractions, the Ringer solution was replaced by physiological saline. There was inhibition of the atrial contraction within a short time. On replacing Ringer solution in the bath the contractions recommenced. Addition of hydrocortisone (kindly made available by Mr. A. V. Mody, Unichem Laboratories, Bombay) to the bath in quantities sufficient to give a final concentration of 25 µgm./ml. resulted in inhibition of the atria. The beats, however, recommenced on changing to fresh Ringer solution, but now replacement of the medium by sodium chloride solution did not result in an early inhibition of the contractions. The inhibitory effect of sodium was significantly postponed by an extremely short pretreatment with the steroid hormone. In fact, in some instances the sodium in the external medium now caused an initial increase in the amplitude of the contraction of the atria. The results are shown in Fig. 1. It is suggested that such an action of the hormone could be due to altered myocardial excitability because of imprisonment of intracellular ions caused by a change in the cell membrane permeability by the steroid.

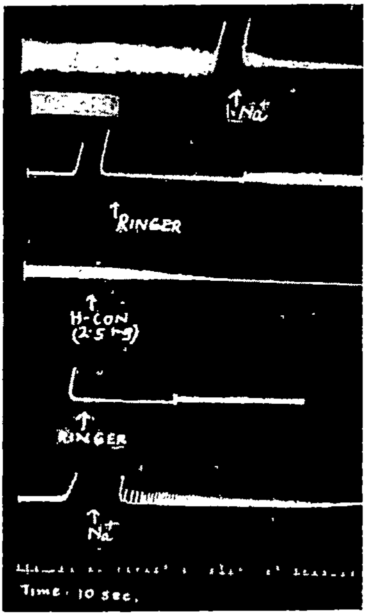

Fig. 1. Effect of hydrocortisone on the action of sodium ions on isolated rabbit auricles

My thanks are due to Mr. N. M. Chavan for all the technical assistance rendered.

Isolation of Active Mitochondria from Apples

IN recent studies on the physiology of ripening in fruits, attention has been focused on the possible relationship between phosphorylative processes and the climacteric rise in respiration[1-3]. Since many respiratory enzymes are located in the mitochondria, the isolation of these subcellular units in an active state is of great importance in such investigations. Although the apple is the classic object for studies in fruit physiology, attempts to prepare particulate fractions with mitochondrial activity from apples have not been successful. Lieberman[4] isolated particles with cytochrome oxidase activity by grinding apples in a medium containing *tris*-hydroxymethyl aminomethane at *p*H 9·2. By using a homogenizing medium buffered at *p*H 7 with 0·5 *M* phosphate, Neal and Hulme[5] obtained apple particles which oxidized succinate and malate to a slight extent, but only in the presence of the phenolic compound protocatechuic acid. Pearson and Robertson[2] isolated apple particles that had a high endogenous oxygen uptake and that showed some oxidative activity with succinate, citrate and malate. Pearson and Robertson's[2] particles were obtained after a single centrifugation of the homogenate and possibly contained contaminating phenolic compounds. These compounds may have contributed in part to the endogenous oxygen uptake and, in the light of Neal and Hulme's[5] results, may also have been responsible for the oxidation of the added acids. In all these studies, stress has been laid on the necessity for counteracting the high acidity of the tissue when preparing mitochondria from apples.

I have overcome a similar difficulty in the banana[6], and prepared active mitochondria by incorporating sufficient dipotassium phosphate into the homogenizing medium to bring the *p*H of the homogenate to 7. When this method was applied to apples, active mitochondria were also obtained.

The procedure was as follows. Ripe apples were placed in a room maintained at about 1° C. at least 2 hr. before being used, and all subsequent manipulations were carried out at this temperature. 200 gm. of diced pulp were extracted with 300 ml. medium in a Waring blendor connected to a rheostat set at 40 V. for 30 sec. The medium contained 150 mmoles sucrose, 3 mmoles ethylenediamine tetraacetic acid and sufficient dipotassium phosphate to bring the *p*H of the mixture to between 7·3 and 7·4. With the varieties of apples studied, 30–33 mmoles dipotassium phosphate were needed for 200 gm. pulp. The mixture was pressed through a layer of muslin and centrifuged at 1,000*g* for 6 min. The supernatant was centrifuged at 20,000*g* for 15 min. The precipitate was suspended in 40 ml. of 0·5 *M* sucrose – 0·01 *M* phosphate, *p*H 7·4, with the aid of a Potter–Elvehjem homogenizer and recentrifuged at 20,000*g* for 15 min. The precipitate was finally suspended in 0·5 *M* sucrose – 0·01 *M* phosphate, *p*H 7·4, and made up to 4–8 ml. with the same solution. The resultant suspension, which was light yellow, dark yellow or yellowish green, depending on the variety of apple used, was tested for mitochondrial activity in a Warburg respirometer at 30° C.

Each Warburg vessel contained: 40 μmoles phosphate at *p*H 7·4; 15 μmoles magnesium sulphate; 6×10^{-5} μmoles cytochrome *c*; 4×10^{-4} μmoles cocarboxylase; 3 mgm. liver coenzyme concentrate; 2×10^{-3} μmoles adenosine triphosphate; 3 mgm. bovine plasma albumen; 40 μmoles glucose; 650 μmoles sucrose; 40 μmoles substrate and 0·5 ml. of the particulate suspension in a final volume of 2 ml. The sources of the biochemicals and the analytical procedures used are described elsewhere[6].

In the absence of added substrate, the apple particles had an oxygen uptake of 0–1 μl. per vessel. The oxidative activity of the particles towards various substrates is shown in Table 1. The succinoxidase activity of the particles isolated from each variety was high. Malate and α-oxoglutarate were oxidized by the particles at a much lower rate than succinate. The ability of the particles from Ohenimuri and York Imperial apples to oxidize citrate is doubtful; the particles from the other varieties oxidized citrate at a rate comparable to that with α-oxoglutarate or malate as substrate. No browning of the reaction mixture was ever observed, an indication that the oxidation of phenolic compounds was not taking place.

Table 1. Oxidative Activity of Mitochondria isolated from Various Apple Varieties. Conditions indicated in Text

Variety	Mitochondrial nitrogen per vessel (mgm.)	$QO_{2(N)}$ with			
		Citrate	α-Oxoglutarate	Succinate	Malate
Golden Delicious	0·51	53	59	106	43
Granny Smith	0·62	44	66	139	62
Ohenimuri	0·20	10	60	220	60
Starking	0·21	86	76	276	133
White Winter Pearmain	0·38	39	63	158	39
York Imperial	0·23	13	39	169	56

The oxidation of pyruvate by these particles could not be demonstrated unequivocally; the oxygen uptake in the presence of pyruvate and catalytic amounts of succinate was only slightly higher than the oxygen uptake with succinate alone.

These apple particles differ from the preparations described in the literature[2,4,5] in having virtually no endogenous oxygen uptake, in their ability to oxidize four members of the tricarboxylic acid cycle, and in the independence of this oxidative activity from polyphenolase activity. It is hoped that further refinement of the procedures described above will lead to the isolation of apple cytoplasmic particles with a full spectrum of mitochondrial activity, as evidenced by their ability to oxidize pyruvate via the tricarboxylic acid cycle and to carry out the concomitant phosphorylations.

This study was supported by a grant from the South African Council for Scientific and Industrial Research. The nitrogen analyses were kindly performed by Mrs. M. C. van Beijma.

Artificial Light and Sexual Maturity in the Fowl

In a recent communication[1] we outlined a general hypothesis to account for the relationship between day-length and sexual maturity in the fowl, *Gallus domesticus*. We have since conducted an experiment which offers striking evidence in support of the hypothesis that sexual maturity is affected by changes in day-length and not by the absolute day-length.

Four groups, each of 150 Rhode Island Red × Light Sussex pullets hatched on December 4, 1957, were reared under identical conditions except for light treatments as follows. Two groups served as controls and received natural daylight only (latitude, 51° 27′ N.): the other two groups were given supplementary lighting to provide continuous illumination during the first week of life and thereafter day-length was reduced by 35 min. each week to reach a level of 14 hr. 5 min. at 17 weeks of age. On April 3 (17 weeks) all four groups were transferred to laying cages where they have been treated uniformly in every respect. Artificial light was not used in the laying house until after the summer solstice, by which time all the birds were in lay.

Table 1. AVERAGE RESULTS TO 37 WEEKS OF AGE

	No. of pullets housed	Age at first egg (days)	Body-weight at:		Eggs per pullet housed: By grades (oz.)			Total
			20 wk. (gm.)	30 wk. (gm.)	$< 1\frac{7}{8}$	$1\frac{7}{8}$–$2\frac{3}{16}$	$>2\frac{3}{16}$	
Controls	285	145·6	2,371	2,772	35·5	24·8	4·3	64·6
Lighted	291	169·7	2,222	2,867	18·3	37·4	7·9	64·1
Difference		24·1*	149†	95†	16·7†	12·6†	3·6†	0·5

* Significant, $P < 0·01$. † Significant, $P < 0·05$.

Average age at first egg is given in Table 1. It is clear that the artificial pattern of decreasing day-length delayed sexual maturity even though it involved the provision of more light than was available to the naturally lit controls. The possibility that long day-lengths, *per se*, inhibit sexual maturity has been eliminated by the work of Hutchinson[2] and others.

In this experiment the net increase in day-length experienced by the controls between hatching and sexual maturity was 6·67 hr. and the net increase experienced by the lighted groups was 8·02 hr. The expected difference in sexual maturity between them, on the basis of the regression coefficient calculated from previous results[1], would therefore be $1·64 \times (6·67 + 8·02) = 24·1$ days. That this agrees so exactly with the observed difference may be coincidental. However, the results of this experiment do agree quantitatively as well as qualitatively with the hypothesis already published. It remains to be seen whether our regression coefficient can be treated as a constant for all stocks.

To measure the benefits which accrue from using lights to delay maturity in pullets hatched in December, records of egg-production, egg-weight, body-weight and mortality will be kept to 450 days of age. Table 1 gives the results up to 37 weeks, and it is apparent that the light treatment has produced an improvement in rate of lay sufficient to offset the 3 weeks delay in maturity. Early egg-size has also been substantially increased, presumably because of the greater body-size eventually attained by the lighted groups.

Full details of this experiment, which is being conducted with the aid of funds provided by the Agricultural Research Council, will be reported elsewhere in due course.

Male Sterility in *Brassica*

MALE sterility has been reported in thirty-one genera[1], but not previously in the genus *Brassica*. In the course of breeding work at this Station male sterile plants have been found in inbred material of three varieties of brussels sprout[2-4]. In one of these varieties one male sterile plant was also found in 5,000 non-inbred plants inspected[4].

Meiotic division in the male sterile plants proceeded normally, but in the majority of anthers pollen development ceased at the tetrad stage, after which the young pollen grains degenerated. At flowering time the anthers were shrivelled (2–4 mm. long). In about 1 per cent of anthers occurring at random on male sterile plants, about 10 per cent of the pollen tetrads continued development to produce apparently normal pollen grains. Such anthers developed to their normal length (10–15 mm. including filament) although they were emaciated and indehiscent. After teasing out such anthers and applying the contents to normal styles, no seed was obtained. The flowers of male sterile plants were usually, though not invariably, smaller and paler in colour than those of normal plants.

This male sterility was found to be inherited as a simple recessive at a single locus. The expression of dominance of male fertility was imperfect, about 25 per cent of heterozygotes producing up to six male sterile flowers (about 1 per cent of the flowers on the plant), usually at the base of the inflorescence. There was some indication that the expression of dominance was affected by temperature, since heterozygotes kept at 70° F. produced more male sterile flowers than others kept at about 55° F.

Male sterility is expected to be of use for the production of hybrid seed in the inbreeding and hybridization programme with brussels sprouts at present in progress at this Station.

Nitrogen Fixation by Non-nodulated Plants, and by Nodulated *Coriaria arborea*

IN a recent communication, Bond[1] discusses the probability that nodulated plants of *Coriaria* fix atmospheric nitrogen in the same way as other non-leguminous nodulated plants with which he has worked. This supposition is confirmed by the results of a trial which was made during the course of other work using nitrogen-15. Wild seedlings of *C. arborea* about 6 in. high, each with a cluster of pink nodules 1–2 mm. long near the crown, were collected from a rocky roadside cutting near Nelson, and grown in quartz sand watered with a minus-nitrogen culture solution. Results from exposing these plants to an isotopically enriched atmosphere are given in Table 1. There was considerable fixation of nitrogen, which may have occurred in the leafy shoots as well as in the roots.

During the past four years I have been investigating the possibility of nitrogen fixation by non-nodulated plants which make vigorous growth in poor soils. Evidence, which is more fully presented and discussed

Table 1

in another publication, has been gathered from three lines of inquiry :

(1) Records of field-experiments published by a number of different workers for the yield of various crops, in relation to fertilizer used and soil nitrogen, over periods of many years, have shown substantial gains of the order of 30–50 lb. nitrogen/acre/year in the absence of legumes or other nodulated plants. Records of native vegetation give similar figures for large, unexplained gains in soil nitrogen. For *Pinus radiata* plantations growing on sand dunes or depleted soils in New Zealand, I made measurements and analyses which showed a gain over twenty-five years of 38 lb. nitrogen/acre/year.

(2) Pot experiments with a number of non-nodulated plants grown in a strictly no-nitrogen medium, in the absence of non-symbiotic nitrogen-fixing micro-organisms, have shown substantial gains in nitrogen over periods of 6 months to 3 years.

(3) Experiments have been carried out with nitrogen-15 in which either whole plants grown in a minus-nitrogen culture in enclosed glass pots, or shoots and roots separately, were exposed to an atmosphere enriched in the heavy isotope. Significant gains in nitrogen-15 have been made by the growing plants, and some typical results are given in Table 1. Leafy shoots (tops) and roots were assayed separately ; figures for control material were 0·003–0·005 atomic per cent excess nitrogen-15 (all figures with respect to cylinder nitrogen).

The evidence from these three lines of investigation leads to the conclusion that a number of non-nodulated plants are able to utilize atmospheric nitrogen. In the case of *P. radiata* and cocksfoot grass, it appears likely that fixation is a function of the mycorrhizas, though it still has to be proved that bacteria in or on these fungal roots are not also implicated. In the case of fixation in the leafy shoots it is possible that bacterial glands are responsible for the effect, but it is also possible that some leaves may yet be found to have a capacity for using nitrogen gas in the absence of micro-organisms.

Effects of Water-Strain on the Minimum Intercellular Space Carbon Dioxide Concentration Γ in Wheat Leaves

In a recent communication, Rees[1] reported that midday closure in the oil palm was associated with water-strain and correlated in extent with total evaporation. There was also a relation with air temperature showing striking stomatal closure between 30° and 35° C., strongly reminiscent of the results of Heath and Orchard[2] for the log Γ/leaf temperature relation in onion and coffee leaves and of those of Heath and Meidner[3] for the stomatal aperture/leaf temperature relation in onion leaves closed at the tip. Rees concludes : "Although increasing leaf temperature may cause stomatal closure, it is clear that midday closure of stomata may also be influenced by water-strain . . .". In work carried out with wheat leaves we found a relation between degree of water-strain and Γ (the minimum intercellular space carbon dioxide content[2]) which is very relevant to this conclusion.

It was found that when detached wheat leaves were subjected to different degrees of water-strain by placing their sheaths in mannitol solutions of different concentrations, Γ values changed very significantly even with leaf temperature and light intensity maintained constant (Table 1).

Table 1. Mean Γ Values (maintained for 20 min.), in Parts per Million of Carbon Dioxide, from Eight Wheat Leaves (Leaf temperature, 25° C. ; light intensity, 900 foot-candles ; relative humidity, 50 per cent)

Successive treatments	0·2 M mannitol	0·4 M mannitol
Water	78	77
Mannitol	94	116
Water	83	82

Significant difference for P 0·05 = 5·9 ; significant difference for P 0·001 = 10·6

Similar increases in Γ were obtained by withdrawing the water supply to produce water-strain, instead of using mannitol, and on restoring the water supply Γ gradually returned to its original level ; the increases recorded in Table 1 are not therefore simply attributable to the mannitol being metabolized by the leaf.

Porometer measurements showed that stomatal closing movements accompanied the increased Γ values produced by water-strain, and some re-opening occurred when Γ fell once more.

These results suggest the existence in the wheat leaf of a carbon dioxide-operated stomatal closing response to water-strain, similar to the carbon dioxide-operated response to high temperature in onion, and probably in coffee leaves, previously discussed[2,3]. In different species midday closure may be mediated by one or the other or both of these mechanisms. Wheat stomata have not in fact been recorded as showing midday closure, and information is not yet to hand as to whether wheat leaves show the sudden increase in Γ with temperature rise above 30° C. found with onion and coffee; stomatal closure does, however, occur in response to dry air[4].

Special significance may be attached to a regularly observed initial decrease in Γ (of about 10 per cent) on placing the leaf sheaths in mannitol solution, which preceded the increase. This decrease was accompanied by the frequently recorded 'passive' initial stomatal opening on wilting. It is possible that epidermal shrinkage, perhaps due to the large 'motor cells', altered the amount of light reaching the chlorenchyma, for it was observed that in this condition the leaves appeared darker suggesting that more light was absorbed. Whatever the mechanism, however, such a temporary decrease in Γ would tend to accentuate stomatal opening—thus the temporary opening on wilting may, in wheat, be in part an effect due to carbon dioxide.

This work was carried out in the Research Institute of Plant Physiology of the Imperial College of Science and Technology, London, with the support of a grant from the Nuffield Foundation. Full experimental details will be published elsewhere in due course, and this line of investigation is being pursued further.

Mode of Intercellular Transfer of Herpes Virus

In previous studies[1] on the growth of the *HFEM* strain of herpes virus in HeLa cells, attempts were made to estimate the proportion of infected cells by inoculating the intact cells on to the chorioallantois of fertile hens' eggs and determining the number which formed pocks. It is known that the chorioallantois is at least ten times more sensitive than HeLa cells to this strain of virus released from HeLa cells. Nevertheless, the proportion of infected (pock-forming) cells was much lower than would be expected from the deduced input of HeLa infective virus, and it was concluded that the cells might not survive long enough to make virus in this environment.

Later, Wildy *et al.*[2] cultured single cells in microdrops of medium and determined the number which released pock-forming virus; the proportion was higher but still less than would be expected, and not related to input of virus per cell over the range tested.

The development by Farnham[3] of a plaque technique in monolayers of HeLa cells under fluid medium has since allowed more accurate determination of the numbers of infecting particles in relation to number of cells. It has also permitted the direct estimation of the number of infected cells by their ability to form plaques (that is, infective centres).

The media and other solutions used and the techniques for preparing cells and virus were as described elsewhere[1,3]. In several experiments monolayers of 3–5 × 10^5 HeLa cells were exposed to 5 × 10^5 HeLa plaque-forming units of virus for 2 hr. The residual virus was removed by treating the cells with antiserum, which was itself removed by washing. This resulted in an input of 2·2 × 10^5 plaque-forming units per monolayer or 0·44–0·78 per cell. The cells, containing virus in the lag phase of growth, were then suspended in sodium ethylenediamine tetraacetate, counted, diluted in maintenance medium, and lots of 50 cells were inoculated on to uninfected monolayers of HeLa cells. Plaques were counted microscopically after 3 days.

In the pooled results of five similar experiments with 27 readings the mean number of plaque-forming cells was 21·8 (standard error ± 1·85) or 43·6 per cent. Variation in the number of cells inoculated gave proportional variation in the number of plaques. When the cells were disrupted by freezing before plating less than 2 per cent formed plaques. The mean input for the five experiments was 0·59 plaque-forming units per cell which, according to Poisson distribution, should result in infection of 45 per cent of cells, so that the method apparently detected most of the infected cells. However, only 7·7 per cent of these cells formed pocks on the chorioallantois.

Concurrent experiments on inhibition of clone formation by single cells taken from monolayers infected with the same virus seed, have shown that the proportion of cells which are prevented from dividing also corresponds to the input of HeLa plaque-forming units[4].

Since mitosis of the infected cells is inhibited, it follows that plaque formation is due to spread of infection to contiguous cells and this might obviously be due to release of virus. When single cells from infected monolayers were isolated in drop cultures, however, the number releasing infective virus was much less than the number of cells which gave rise to plaques. Thus in experiments with the same seed and dose as in the series quoted, where 43·6 per cent of cells formed plaques, none out of 30 cells released virus infective for HeLa cells, and only 3 in 80 (4 per cent) released virus detectable on the more sensitive chorioallantois.

If very few infected cells release virus capable of infecting HeLa cells or even chick cells, how then does the virus spread to the contiguous cells in a monolayer to cause the typical cytopathic effect? It is known that addition of antiserum after virus adsorption does not prevent the development of a plaque, which suggests that it does not depend on spread of released virus passing from cell to cell through medium. In addition, it has now been found that infected cells initiated plaques when they were added to monolayers in medium already containing strong antiserum. In two experiments 24 per cent and 10 per cent of cells formed infective centres in patients' antiserum (pock neutralization index 10^4) against 50 per cent and 36 per cent respectively in normal serum.

Multinucleate syncitia are a constant finding in HeLa cells infected with the *HFEM* strain of herpes virus, and it has been shown that these are due to cell fusion rather than nuclear division (ref. 5 and Stoker, M. G. P., and Newton, A., unpublished). The herpes plaque in its early stages consists, in fact, of a single syncitial mass with many nucleic and no intervening cell walls. These fused cells may be observed as early as 9 hr. after infection, and it is therefore possible that the virus spreads by fusion of an infected cell with its uninfected neighbours.

If virus does spread from cell to cell in this way by fusion of the cytoplasm it might be transferred as infective, but unreleased, virus particles, or alternatively, in a vegetative, non-infective state. If it is due to infective virus, the latter ought to be detectable as such by disintegration of the cells at the end of the growth period.

Single cells from a monolayer infected as above were isolated in micro-drops and were burst by a single cycle of freezing and thawing after incubation for 30 hr., which was previously shown to be the optimal time for detecting released virus in single-cell cultures[2]. Only one cell in 130 (0·8 per cent) released HeLa-infective virus under these conditions, despite the fact that 43·6 per cent of the intact cells could give rise to plaques. In other experiments with a higher input (1·0 plaque-forming units per cell) and using the more sensitive pock assay, only 4 cells in 80 (5 per cent) released virus after freezing.

More thorough methods of cell disintegration and other sampling times will be needed to confirm the absence of infective virus in the majority of plaque-forming cells, but these results do raise the possibility that vegetative herpes virus can spread from cell to cell.

Responses of Insects to Polarized Light in the Presence of Dark Reflecting Surfaces

The ways in which arthropods, such as bees[1–3], ants[4,5], Diptera[6], insect larvæ[7], Cladocera[8,9], Amphipoda[10] and Decapoda[11], orientate in respect to the plane of vibration of polarized light are controversial. Some authors have investigated by optical and electrophysiological means various arthropod eyes and their elements for the properties of an analyser[12,13], either those of a Nicol prism or those of some internal reflexion device; whereas others have been more concerned with external visual conditions[3] in which orientation to polarized light is observed, and have tried to explain it on the basis of mere brightness discrimination. The present communication has followed the latter approach and was based on the following considerations.

The three responses thus far used in demonstrating effects of light polarization, namely, the linearity of tracks, their angular orientation to the plane of polarization and responses to single sudden changes of this plane, are not phenomena which are very striking. It was thought that clearer results might be obtained in situations where continuous rotation of the plane of vibration would, by vectorial summation[14], induce strong rotatory optomotor reactions. Such a situation is provided in the apparatus shown in Fig. 1. This apparatus consists mainly of two coaxial circular turntables which can be moved independently of each other. On the upper one (drawn in black), which is mostly kept stationary, is placed an insect enclosed between two watch-glasses about 5 cm. in diameter. This turntable also carries a black cylinder and diaphragm shielding the insects from stray light. The lower and larger turntable carries a black cylinder covered either by a 'Polaroid' sheet or by a transparent sheet of plastic crossed in the middle by a black strip 3 cm. wide. This lower turntable can be turned by hand in either direction. The apparatus is placed in a dark room, 100 cm. beneath the open end of a piece of stove-pipe, 60 cm. long, which contains near its upper end a light bulb of about 100 W. Only about half the watchglass is visible to the observer when the apparatus is in position, and thus the direction of movement of an insect in it can be noted as it comes into view.

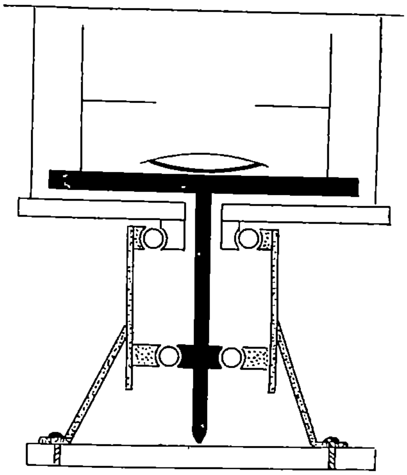

Fig. 1

Many species of flies, ants and moths were found to react to the rotation of light polarization. Table 1 summarizes the results of six typical experiments, each involving forty observations. It shows that (1) rotation of the plane of vibration induced clear optomotor reactions, but that (2) these occurred only in special visual circumstances, for example, when

the hollow of the lower watchglass was coated with black passe-partout (gum strip), whereas on a light background either no reaction or only a weak one occurred. Table 1 also shows that (3) optomotor responses similar to those induced by the 'Polaroid' were observed after a clear sheet carrying a black strip was substituted for it. The polarized light reflected from a white background towards the centre of the watchglass, where the insect's eyes were, is largely depolarized, and no great differences of intensity occur in different directions. On the other hand, a great deal of light is reflected from the black passe-partout in the plane of vibration, but very little vertically to it. Rotation of a 'Polaroid' thus results in the rotation of a light band in the dark part of the visual field of the insect. This effect can easily be demonstrated to the unaided human eye by means of a somewhat larger model. Findings (2) and (3) confirm the conclusions, derived from quite different experiments, of Baylor and Smith[8] on bees, namely, that some motor responses in insects are not induced by the polarized light directly perceived, but by light reflected from a dark background.

The above experiments do not, of course, preclude the possibility that the eyes of some arthropods, and perhaps of other animals, may have true analyser properties. Faint visual effects, comparable in intensity to the perception of Haidinger's figure by man[15], possibly occur widely; and stronger effects may occur in eyes possessing bulging lenses, like those of the Cladocera or of the tadpoles of *Xenopus*, where simple internal reflexion may operate[3]. Bees flying under large areas of polarized light from the sky[1] and insect larvæ crawling in the open[7] seem to react overtly to these large-scale patterns. On the other hand, in certain circumstances, when polarized light from a small source is reflected from dark reflecting surfaces, as in von Frisch's bees dancing on a horizontal comb[1,2], or in Santschi's ants crawling on sand inside a dark tube[4], maintenance of the perceived reflected light pattern provides a sufficient explanation. Attempts to explain reactions to light polarization by means of special, optical and nervous arrangements in the eye concerned and to demonstrate their existence by electrophysiological means, should in future be confined to visual situations, where the above explanation does not apply.

I wish to thank Prof. B. Hocking and Mr. W. Klaassen of the University of Alberta for help in these experiments, and Dr. E. R. Baylor of Woods Hole for sending me his mimeographed lecture notes.

An Artificial Diet for the Laboratory Rearing of Locusts

Locusts are being increasingly used for research and teaching purposes, but one of the main difficulties involved in maintaining a culture is the provision of an adequate supply of fresh green grass throughout the year[1]. A further disadvantage of this grass diet was revealed by biochemical investigations into the variation with age of the concentration of reducing substances in the hæmolymph of *Schistocerca gregaria* Forsk., to be reported elsewhere. The above pattern of variation was partially masked by the considerable divergence of many results from the mean values. In view of these divergences, which were thought to be due to differences in the quality of the grass diet, an artificial diet was formulated. The use of this diet, to which very small quantities of fresh green grass were added, considerably reduced these divergencies.

Three series of experiments were later carried out in order to determine the effect of rearing both the desert locust *Schistocerca gregaria* Forsk. and the African migratory locust *Locusta migratoria migratorioides* (R. and F.) on (*a*) artificial diet alone, (*b*) artificial diet plus fresh green grass added once a week for 24 hr., and (*c*) artificial diet plus a very small quantity of fresh green grass given daily. In each series an equal number of control cages were set up in which the locusts were fed on fresh green grass given daily.

In all experiments the two species *L. migratoria* and *S. gregaria* were reared in initial batches of 20 in 12-litre cages of plastic and metal, kept in a constant-temperature room at 28° C., the temperature in the cages being 34–36° C. during the day and falling to 28° C. at night. This day temperature was maintained by placing five cages around each 100-watt bulb, which was on from 9 a.m. to 4 p.m. The relative humidities in both the control and artificial diet cages were 55–60 per cent in the mornings and 45–50 per cent in the late afternoons. Twigs, which were scarcely eaten during the course of the experiments, were placed in each cage to facilitate moulting by acting as perches. Each cage also

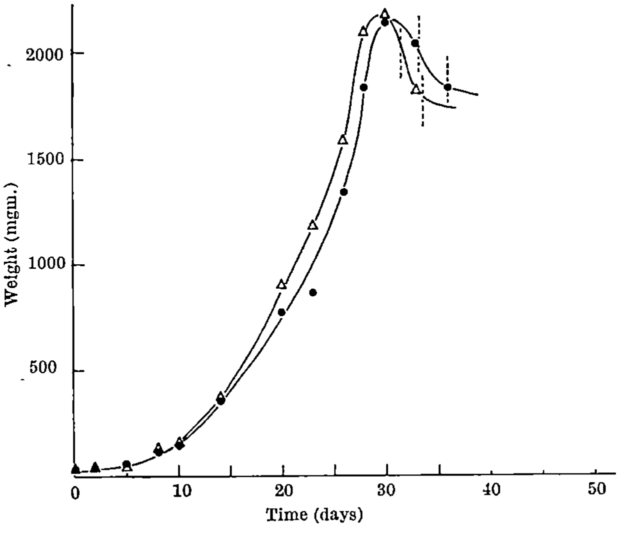

Fig. 1. Growth curves for *S. gregaria* females, series 1. —△—, Control (grass) diet; —●—, artificial diet. Final moult is indicated by broken vertical lines

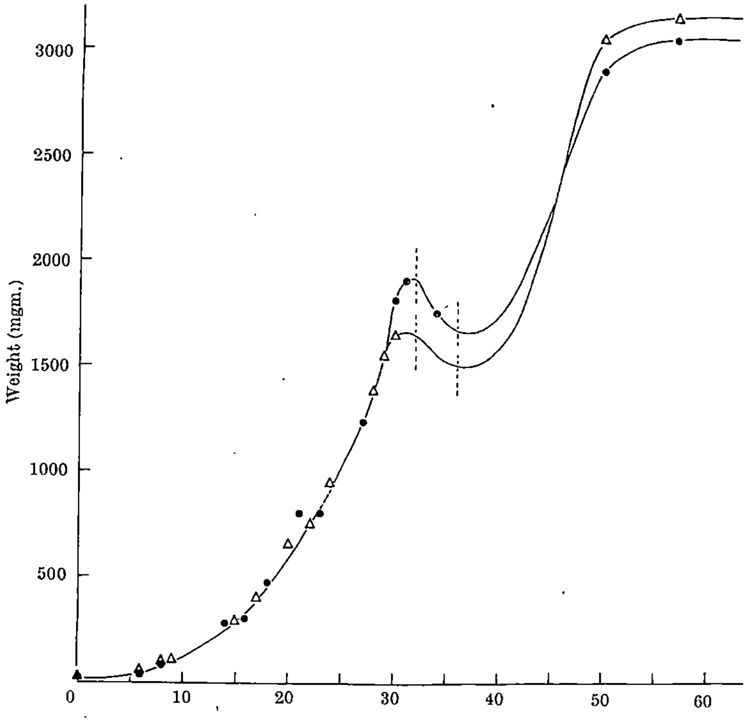

Fig. 2. Growth curves for *S. gregaria* females, series 3. —△—, Control (grass) diet; —●—, artificial diet. Final moult is indicated by broken vertical lines

had a dish containing cotton-wool soaked with water.

The artificial diet was offered as a dry mixture of the following composition: bran, 2; dried whole milk, 2; grassmeal, 2; dried brewers' yeast, 1 (parts by volume). The results of the first series of experiments in which artificial diet was fed to the experimental group of locusts are shown in Fig. 1.

Although the growth curves and weights at the final moult were similar for both the experimental and control groups of *S. gregaria*, the coloration of these groups differed. The normal pink coloration of the sexually immature adults was lacking in the experimental group of locusts, as was the yellow normally characteristic of sexual maturity. Further, a previous experiment had shown that although eggs were laid by these locusts, they were not viable. The mortalities were also significantly different, being 30 per cent in the control group and 80 per cent in the experimental group of *S. gregaria*. In each species the males and females showed similar mortalities.

The results of the second series of experiments in which a large quantity of fresh grass was provided once a week for 24 hr. were not so good for either species as those of series 1. There were considerable differences in the growth curves, the weights at the final moult, the times of development and the mortalities. However, the coloration of both sexually immature and mature adult experimental *S. gregaria* was the same as that of the controls.

The third series of experiments provided the best results. In these, artificial diet mixed with chopped-up grass was fed daily to the experimental locusts. The amount of grass supplied to each cage, in blades about ⅛ in. wide, was equal to the sum of the lengths of locusts in that cage. Fig. 2 shows the growth curves for experimental and control females of *S. gregaria*.

In each species results for males and females were similar. With *S. gregaria* there was a tendency for the final moult of the experimental locusts to occur a few hours before and at a slightly greater weight than that of the controls. The mortalities were very nearly the same, averaging 28 per cent for the experimental locusts and 23 per cent for the controls. No difference in coloration could be detected up to the end of the sexually immature adult stage, although the normal yellow colour of the sexually mature males was acquired by the experimental locusts one week later than by the control group. Once the locusts were mature, the rate of laying of egg pods was the same, as was the period of incubation and the weight and colour of the emerging hoppers.

With *L. migratoria* the results for the three series of experiments were not so good, since the times of development were increased, the weights of all stages were reduced and the mortalities of experimental *L. migratoria* were considerably greater than those of the control group. These results are compatible with the fact that, in the field, the African migratory locust feeds mainly on grass whereas the desert locust does not.

It is therefore suggested that this artificial diet plus a small daily addition of fresh grass may be of use in maintaining cultures of *S. gregaria* in places where large quantities of fresh grass are not available throughout the year, the amount of grass required daily being of the order of 2–3 gm. for 50 adult locusts and correspondingly less for the preceding instars. The artificial diet alone may be useful in physiological and biochemical investigations on one instar where variations in diet tend to mask the changes due to development. In more extended studies the use of small quantities of a single species of grass grown throughout the year, in addition to the artificial diet, may also eliminate seasonal variations in diet. Full details of this work will appear elsewhere.

One of us (G. F. H.) wishes to thank the Agricultural Research Council for financial support in the initial stages of this work, and Prof. F. C. Happold and Dr. B. A. Kilby for their advice and encouragement, and for the hospitality of the Department of Biochemistry of the University of Leeds.

Albinism in the Migratory Grasshopper, *Melanoplus bilituratus* (Wlk.)

HUNTER-JONES[1] discovered albinism in the desert locust, *Schistocerca gregaria* (Forsk.), and established an albino strain of this species. A single, nearly colourless, male of the migratory grasshopper, *Melanoplus bilituratus* (Wlk.)—formerly known as *M. mexicanus mexicanus* (Sauss.)—appeared in a culture at the Saskatoon laboratory in 1954. Although the characteristic as observed in this individual and his descendants may not conform to the strict definition of albinism, the term is retained here for its convenience.

The nearly colourless male was mated with a number of normal females of the same species, and the resulting F_1 progeny were all normally pigmented; the F_2 progeny contained a minority of grasshoppers resembling the albino parent, but the observed ratio of normal and albino individuals could not be reliably interpreted on a genetic basis. Later, male albinos were back-crossed to phenotypically normal F_1 hybrid females, and a progeny of about 500 was produced. This progeny was divided in the ratio of 238 albino : 257 normal ($\chi^2 = 0{\cdot}365$; $P = 0{\cdot}6$, basis 1 : 1 hypothesis). When both parents were albinos, only albino progeny were produced. The genetic basis of the albinism is therefore probably a single recessive gene.

In a mixed population of nymphs, albino individuals are not distinguishable by any means yet discerned until after the first nymphal moult; they are then unmistakable, though a slight expression of melanism persists. For example, the chevron pattern on the femora remains faintly discernible. In adults, a certain amount of rather diffuse melanic pigment appears and tends to intensify with age, although albino individuals remain easily distinguishable from normal ones throughout the adult life.

Albinos of *M. bilituratus* reared in the laboratory appear to grow as rapidly and to show the same degree of robustness and activity as normal individuals. In pure culture they appear to mate normally but a vigorously multiplying stock has not yet been produced; presumably egg production, or the viability of the eggs, is subnormal. Most of the albino individuals obtained have therefore been produced by matings involving at least one heterozygous parent. By successive breeding back to normal stock, it is hoped to overcome the apparent difficulties now encountered in maintaining a pure culture of albinos.

The survival value of the albino characteristic under natural conditions in western Canadian altitudes would be expected to be low, if only because individuals having the characteristic would presumably be unable to benefit from insolation to the same extent as the rather heavily melanized grasshoppers in the normal population.

A New Type of Insecticide

RECENTLY, I found[1] that strains of *D. melanogaster* characterized by resistance to DDT, BHC, parathion and other insecticides were susceptible to phenylthiourea, while the majority of strains susceptible to DDT were resistant to phenylthiourea.

In previous papers[2,3] the genetical relation between resistance to phenylthiourea and to other insecticides has been discussed and the hypothesis was introduced that the dominant gene on the second chromosome, which confers resistance to DDT, BHC and parathion, also confers abnormal susceptibility to phenylthiourea. The dominant gene on the third chromosome which confers resistance to nicotine sulphate also confers resistance to phenylthiourea.

Accordingly, it may be presumed that susceptibility to phenylthiourea results from the pleiotropic expression of the dominant gene for resistance to DDT, BHC and parathion on the second chromosome. This assumption suggests that the mixture of DDT, BHC or parathion with a substance correlated negatively to these compounds, such as phenylthiourea, might have an effective insecticidal action and might not produce flies resistant to these mixtures even after continuous use.

In order to test this assumption, the following backcross was carried out by using a strain resistant to DDT and nicotine sulphate (Hikone-*R*31 wild

PTU 5·0 m*M* DDT 2·0 m*M*	0	0	0	0

The following abbreviations are used: *R*—DDT, DDT-resistant gene on the second chromosome; *R*—*NS*, nicotine sulphate-resistant gene on the third chromosome; *S*, susceptible; *R*, resistant; PTU, phenylthiourea.

strain) and a strain susceptible to DDT and nicotine sulphate (*bw* ; *st ss*, multichromosomal mutant strain):

bw ; *st ss* ♀ × F_1 (*bw* ; *st ss* ♀ × Hikone-*R*31 ♂) ♂

The relation between the phenotypes and the number of surviving flies emerging from treated media was studied by using the larval test method[3]. Some of the results are shown in Table 1.

These results indicate that the mixed insecticide has a severe action even on flies exhibiting resistance to many kinds of insecticide. All strains of *D. melanogaster* were killed by exposing them to the mixture of the minimum amount of phenylthiourea which kills strains resistant to DDT and of the lowest amount of DDT which is enough to kill strains resistant to phenylthiourea (that is, susceptible to DDT).

Further experiments on the dosage from the point of view of population genetics are now in progress, and a more detailed report will be published elsewhere. I am greatly indebted to Prof. H. Kikkawa and Mr. M. Tsukamoto for supplying the strains resistant to insecticide.

Fire-blight of Pear in England

THE presence of fire-blight of pear, an extremely destructive bacterial disease caused by *Erwinia amylovora* (Burrill) Winslow *et al.*, has recently been confirmed in England. This represents the first authenticated record of the disease in Europe.

Fire-blight is indigenous to North America and has been known for more than 150 years in the United States, where it is still a major factor limiting the successful cultivation of pear in certain areas. Elsewhere it occurs only in New Zealand; it appeared there about 1919 and in the next ten years spread to most fruit-growing areas of the Dominion. In addition to pear, the disease attacks apple and other related hosts, for example, quince, hawthorn, mountain ash, *Cotoneaster*, *Pyracantha* and various ornamental *Pyrus* spp.

The first intimation of the present outbreak was received during the late summer and autumn of 1957, from five fruit farms in the Maidstone, Wrotham and Rochester areas of Kent. Many pear trees of the variety Laxton Superb were then dying and on several others main branches had been killed by extensive cankers present on the branches and stems. In 1958 there was a further considerable spread of the disease in some of the affected orchards, and two completely new outbreaks were identified in the Rochester area.

Infection begins in the blossom, particularly the secondary blossom formed after the main spring flowering period. Diseased flower trusses turn black and the infection spreads rapidly into the branches causing a necrosis of the superficial cortical cells. The branches are eventually killed, the leaves wither and turn dark brown or black, and badly affected orchards then appear as if they have been swept by fire. The progress of the infection is halted towards the end of the season, but by this time it may have reached the trunk of the tree. Cracks now appear at the margins of diseased and healthy tissues and typical cankers are produced. In some of these cankers the bacteria survive the winter and renewed invasion of adjacent healthy tissues begins in the spring.

During the growing season, shoots and fruits may be attacked. These have an oily appearance at first but later they turn black in the same way as blossom. The fruits become wrinkled like a prune, and in humid weather they and the shoots exude a whitish bacterial ooze which turns amber after exposure.

The disease has been so destructive on Laxton Superb that one small orchard, consisting mostly of this variety, no longer has any commercial value. Conference, Dr. Jules Guyot and Bristol Cross have also been attacked, but so far only a few trees of these varieties have been involved. Williams Bon Chretien (*syn.* Bartlett), a variety often badly damaged by fire-blight in the United States, has so far remained virtually unaffected in the field, although it has shown little resistance in inoculation experiments.

Isolations made during this year from diseased branch, shoot, fruit and blossom tissues yielded the same organism, forming cream-coloured hemispherical colonies on a nutrient agar containing 5 per cent sucrose. The cross-infectivity of these isolates has been demonstrated in an extensive series of inoculation experiments. Symptoms on pear shoots and fruits were identical with those described for *E. amylovora*, the most characteristic feature being the production of white globules of bacterial ooze on the surface of infected tissues under humid conditions. Apple fruits, and apple and hawthorn shoots have also been successfully infected.

The pathogen is a Gram-negative peritrichous rod of the genus *Erwinia*, closely resembling authentic strains of *E. amylovora* in culture. The close affinity of the two organisms is also shown by tests with bacteriophages, isolated from soil in one of the diseased orchards by a method previously described[1]. Thus, among a wide range of *Erwina* and *coli-aerogenes* species examined, the phages were specific for the present pear isolates and *Erwinia amylovora*, including a strain of the latter tested at the New York State Agricultural Experiment Station, Geneva, U.S.A., by Dr. R. M. Gilmer.

Autoradiographic Analysis on Agar Plates of Labelled Antigens from Rat Liver

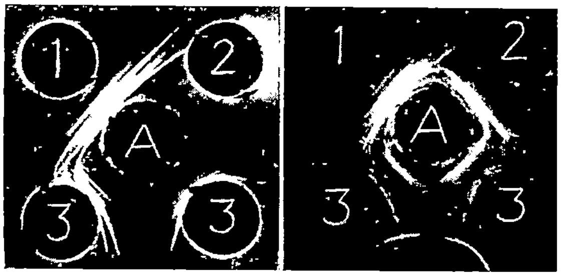
IN the study of protein metabolism it is often essential to be able to refer the incorporation of isotopic amino-acids to some individual type of protein, characterizable, for example, by means of a particular enzymatic activity or by its antigenic specificity[1]. As shown previously, soluble proteins derived from microscopic and submicroscopic fractions of liver cells can be characterized immunologically by means of precipitin reactions in agar plates[2]. In order to analyse some of the early pathways occurring in protein metabolism under various conditions, an attempt was then made to combine this method of protein identification with autoradiography in isotope incorporation experiments. A short account of the procedure and the results obtained are given in this communication[3].

Rat liver slices, about 0·3 mm. thick, were incubated for 30 min. in a Krebs–Henseleit medium in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide. The medium, fortified with glucose, contained per ml. 0·015 µmole L-leucine-^{14}C (11·5 mc./mmole), 0·02 µmole of L-valine-^{14}C-(8·5 mc./mmole) and 0·065 µmole of DL-tyrosine-^{14}C (0·09 mc./mmole). The incubation was performed in tubes containing 40 mgm. of slices (fresh weight) per ml. of solution. After the incubation the slices were washed and homogenized in ice-cold 0·25 *M* sucrose. Microsomes and the soluble fraction were prepared by means of differential centrifugation[4]. The microsomal fraction was extracted with 0·4 per cent sodium deoxycholate[5]. Before further use, the solutions were diluted to contain approximately 4–6 mgm. protein/ml., determined according to Lowry *et al.*[6].

The immunological experiments were performed with antisera from rabbits, previously injected with total homogenate, microsomes or the soluble fraction ('supernatant') of rat liver. The mode of preparation of the antisera and the method of double diffusion in agar have been described previously[2].

After completion of the serological reactions the agar plates were freed from salts, amino-acids and excessive protein by prolonged washing with buffered saline and with water. After desiccation, the glass slides with the thin agar film on top were placed in contact with a photographic emulsion (Ilford, X-ray film, double coated) and left in the dark room for ten weeks. The autoradiographs were then developed in the usual way. Finally, the immunological precipitates were stained with azocarmin *B*[7], mounted with liquid plastics and the precipitation patterns recorded photographically.

Figs. 1 and 2 show the results of an experiment where the deoxycholate extract of microsomes was allowed to react with the various antisera mentioned above. Fig. 1 shows the normal spectrum of precipitates already described[2]. Fig. 2 presents the autoradiograph of the same experiment. Obviously, a high incorporation has been obtained of the amino-acids labelled with carbon-14 into the immunologically distinct proteins, extractable from the microsomes with deoxycholate. Moreover, the method has a good resolving power; the radioactivity is entirely concentrated to the different antigen–antibody precipitates, which show up almost as sharply in the autoradiograph as they do in the original plate.



Figs. 1 (left) and 2 (right). Precipitin reactions in agar-gel. Antigens diffusing from the central basin, antisera from the peripheral basins. Fig. 1 shows the print obtained by placing the dried agar film with the stained precipitates directly into the photographic enlarger. Fig. 2 shows the autoradiograph of the same plate. *A*, Deoxycholate extract of microsomes; 1, anti-microsomal serum; 2, anti-supernatant serum; 3, anti-total homogenate serum

As can be seen from Fig. 2, two strongly labelled precipitation lines were obtained in the reaction between the microsomal extract and the anti-supernatant serum. One of these also appeared between the extract and the anti-total homogenate serum. It is of great interest that the corresponding precipitates were scarcely visible in the original plate (cf. Fig. 1.) Although care must be taken in the interpretation of band-densities in the Ouchterlony reaction, there was good evidence to indicate that the amount of antigen in these heavily labelled precipitates was very low. Hence, it may be concluded that these two precipitates represent two groups of metabolically particularly active proteins.

The experiment described in this communication may be sufficient to illustrate the usefulness of a combination of autoradiography with immunological agar techniques for the qualitative and semi-quantitative analysis of protein metabolism in highly complex systems. Further studies on this method and its application are in progress.

Coat-Colour and Longevity in Thoroughbred Mares

AUTHORITIES differ on the reality and consistency of differences in temperament and performance between horses of different colours[1,2]. Scheiermann[3], in a paper not available in Britain, has reported significant differences associated with colour in the working life of Rhenish horses. I have recently constructed life-tables for English thoroughbred mares, using the data contained in the General Stud Book, as part of a comparative study of the rates of actuarial ageing in mammals. Details of this work will appear elsewhere[4]: it was based on the 11 annual cohorts of brood mares foaled in 1860–64 and 1875–80 from the time of their entry at stud (average age 4 years). Of these 11 cohorts, 5 (1875–79) were scored for coat colour: of 1,271 mares composing them, 568 were bays, 181 browns, 262 chestnuts, 27 blacks, 5 greys, 3 roans and 2 grey roans, the balance being of doubtful or unstated colour. For comparison of the rarer coat-colours among thoroughbreds, further records of greys and blacks were taken by a search of the remainder of the Stud Book.

The mean and median expectations of life from 4 years of the various coat-colours, of the 1860–64 and 1875–80 samples, and of the individual cohorts making up the second of these, are given in Table 1. No separate life-table was calculated for brown mares, because of the probable diversity of coat-colours included in this description.

Table 1. Longevity and Survival by Coat-colour of Thoroughbred Mares

Group	n	$e_{x=4}$	V_e	Median
All colours :				
Foaled 1875	285	17·26	0·34	22·43
1876	245	17·65	0·21	22·43
1877	233	17·44	0·21	22·49
1878	248	17·49	0·30	22·15
1879	261	16·13	0·16	20·81
1880	221	16·01	0·18	21·81
1875–80	1,492	17·04	0·046	22·18
1860–64	1,250	17·31	0·044	22·07
Bays (1875–79)	568	16·68	0·08	22·03
Blacks (1854–1900)	358	16·53	0·15	21·95
Chestnuts (1875–79)	262	17·23	0·20	22·50
Greys (1845–1920)	200	15·57	0·28	20·43

Of the colour groups examined, only greys appear to diverge significantly from the mean expectations calculated for all mares, the difference being greater than those found between annual cohorts ($P < 0{\cdot}01$). Owing to the way in which the data were obtained, factors of selection cannot be entirely excluded ; the difference in the period from which lives of greys were drawn does not appear to be responsible for their shorter life, since there is no significant difference between the early and recent chronological halves of the sample. Greys have been selectively exported at most periods, compared with other coat-colours : they therefore show a rather higher percentage of losses to the record. Most of the reduction of their expectation of life is due to early deaths (< 10 years), the expectations of further life at 10 and 15 years being 10·96 and 3·85 years in greys as against 11·17 and 2·93 years in all mares of the 1875–80 sample. Causes of death were not recorded, and there is consequently no information about the prevalence of benign or malignant melanomata, to which grey horses of certain breeds are subject[5].

Grey thoroughbreds in the Stud Book are the progeny of a relatively small number of stallions compared with other colours, but none of these contributed sufficient progeny dying at a known age for the life-tables of his grey and non-grey fillies to be satisfactorily compared. Further studies of the Stud Book may indicate whether the apparent shortening of the life of grey thoroughbreds is real, and with what other factors it is correlated.

This work was undertaken during the tenure of a Nuffield Research Fellowship in Gerontology.

Temperature Dependence of the Conductivity of Electrolyte Solutions

It has been known for some years that the ionization constant, K, of weak acids reaches a maximum value at a certain temperature T_m, which is defined by $T_m = \sqrt{(A_1/A_3)}$ if K is given by the following function of the absolute temperature[1] :

$$\ln K = -\frac{A_1}{T} + A_2 - A_3 T \qquad (1)$$

Here A_1 and A_3 are positive constants, while A_2 may be positive or negative. Equation (1) is valid for all kinds of solvents.
